Abstract:

Contemporary soil tests for K often do not predict K supply characteristics of the soil which influence K phytoavailability, such as K in solution, K buffering capacity, rate of K supply, and K exchange equilibria. The major challenge in elucidating the soil-solution-plant system has been extracting the unaltered soil solution at soil water contents under which plants grow. Procedures have only recently been developed and can now be used to help elucidate this system.

Immiscible liquid displacement and K adsorption isotherm techniques were employed to characterize K supply characteristics of the soil by chemical and thermodynamic indices. Treatments consisted of seven rates of K (0 to 800 mg/Kg), three rates of Cu and Cd (0 to 400 mg/Kg), two soil moisture contents (19 and 25%) and temperatures (5 and 200, and six equilibration times (.25 to 336 hr) applied in complete factorial combinations. The soil used was the Ap horizon of Bozeman silty clay loam (Typic Argiborolls). Concentrations of K, Ca, Mg, Cu and Cd in the soil solution and on the exchange sites were determined and various relationships were calculated.

A schematic description of soil-solution system in relation to soil K availability was developed in response to each treatment. Adding K increased K availability by increasing the K activity and buffering capacity but decreased the role of diffusion to supply K to crop and the affinity of the soil for K. Increasing Cu and Cd additions increased the activity of K in the solution and selectivity for K, but decreased K adsorption, buffering capacity and role of diffusion in supplying K to roots. Thus, larger applications of K fertilizer would be required for a soil contaminated by Cu and Cd to maintain the availability of labile K in the solution. Increasing soil water contents decreased the activity of K in solution, but increased K adsorption; thus, buffering capacity, the role of diffusion to supply K, and selectivity for K. Increasing soil temperature increased the activity of K in the solution but decreased the K adsorption; thus, buffering capacity, and selectivity for K. The adsorption-exchange equilibria were established rapidly.

The immiscible liquid displacement technique proved to be a convenient and precise method to characterize the soil-solution system with respect to soil K availability.

ACKNOWLEDGEMENTS

I express my most sincere appreciation to Dr. Earl O. Skogley, my major professor, for the project, assistance, encouragement, kindness, and advice during my period of study and research for the Doctorate and the preparation of this dissertation. I thank the members of my committee, Dr. A. Hayden Ferguson, Dr. Paul O. Kresge, Dr. Dwane G. Miller, and Dr. Ralph A. Olsen for their advice, guidance and encouragement lending a great contribution to this dissertation. Thanks also to Dr. Norman D. Reed, who served as a representative of the College of Graduate Studies on my thesis committee.

My wife, Kyungsook, and children deserve my special thanks for providing inspiration and a warm and happy home. Special thanks to my parents and family in Korea for their spiritual and financial support during the period of my staying in a foreign country.

I thank many graduate colleagues, staff, and faculty members for their camaraderie and help.

ABSTRACT

Contemporary soil tests for K often do not predict K supply characteristics of the soil which influence K phytoavailability, such as K in solution, K buffering capacity, rate of K supply, and K exchange equilibria. The major challenge in elucidating the soil-solution-plant system has been extracting the unaltered soil solution at soil water contents under which plants grow. Procedures have only recently been developed and can now be used to help elucidate this system.

Immiscible liquid displacement and K adsorption isotherm techniques were employed to characterize K supply characteristics of the soil by chemical and thermodynamic indices. Treatments consisted of seven rates of K (0 to 800 mg/Kg), three rates of Cu and Cd (0 to 400 mg/Kg), two soil moisture contents (19 and 25%) and temperatures (5 and 20C), and six equilibration times (.25 to 336 hr) applied in complete factorial combinations. The soil used was the Ap horizon of Bozeman silty clay loam (Typic Argiborolls). Concentrations of K, Ca, Mg, Cu and Cd in the soil solution and on the exchange sites were determined and various relationships were calculated.

A schematic description of soil-solution system in relation to soil K availability was developed in response to each treatment. Adding K increased K availability by increasing the K activity and buffering capacity but decreased the role of diffusion to supply K to crop and the affinity of the soil for K. Increasing Cu and Cd additions increased the activity of K in the solution and selectivity for K, but decreased K adsorption, buffering capacity and role of diffusion in supplying K to roots. Thus, larger applications of K fertilizer would be required for a soil contaminated by Cu and Cd to maintain the availability of labile K in the solution. Increasing soil water contents decreased the activity of K in solution, but increased K adsorption; thus, buffering capacity, the role of diffusion to supply K, and selectivity for K. Increasing soil temperature increased the activity of K in the solution but decreased the K adsorption; thus, buffering capacity, and selectivity for K. The adsorption-exchange equilibria were established rapidly.

The immiscible liquid displacement technique proved to be a convenient and precise method to characterize the soil-solution system with respect to soil K availability.

INTRODUCTION

Soil potassium can be divided into four categories: (1) Soil solution K; (2) exchangeable K; (3) difficultly exchangeable K; and (4) mineral K. Most soils have relatively large contents of total K but relatively small amounts of phytoavailable K. Potassium ions move from one category to another at greatly different rates and availabilities whenever equilibrium is disturbed by plant K uptake and K fertilization.

Throughout Montana crops have frequently responded to K fertilizers on soils testing "high" in NH_4OAc -extractable K. Worldwide, contemporary soil tests for K do not perform well for the purpose of predicting crop response to K fertilizers under many soil and climatic conditions. This is probably partly due to the underestimation of the true magnitude of crop demands for K, which differs greatly from that amount of K actually removed by a mature crop. Additionally, soil test procedures do not account for mechanisms of K movement in soils, some of which can limit K availability. Better ways of testing soil to evaluate true soil K availability are clearly needed.

Phytoavailability of soil nutrients can be determined by understanding the nutrient supply characteristics of soils and the nutrient absorption characteristics of plant roots. Soil parameters influencing cation nutrient availability are (1) the activity (or concentration) of nutrients in soil solution, (2) the buffering capacity of the soil for a given nutrient ion, (3) exchange equilibria among ions, and (4) diffusion and mass flow rates through the soil. Plant

parameters depend on root system sizes, characteristics, transport mechanisms, and physiology.

Many studies have been reported relative to plant parameters of nutrient availability as well as methodologies for measuring soil aspects of nutrient availability. The soil-K-plant system is highly complex and influenced by numerous conditions. One of the major limitations to our knowledge in this area probably derives from the complexities of understanding the soil-solution-plant relations. A major challenge in elucidating chemistry of soil nutrient availability is the removal of soil solution, equilibrated with soil, without altering the solutions' chemical compositions. Numerous methods have been proposed based on the principles of suction, pressure, compaction, column displacement, and centrifugation. However, separating the unaltered soil solution from the solid phase of soil has been difficult due to the several limitations involved in each procedure. Establishment of chemical indexes for soil aspects of nutrient availability based on a reliable method of solution extraction would represent significant progress in better understanding soil-solution-plant relations with respect to soil K availability. Procedures for extracting the real representative soil solution without changing its chemical compositions have only recently been developed.

The immiscible liquid displacement (ILD) method, which combines the principles of simple centrifuge method with immiscible displacement, is one of the most convenient and reliable techniques to extract the representative soil solution with a minimum of errors and is a promising

technique from which to characterize the soil as a medium for plant growth.

Several factors are known to affect soil K availability and exchange equilibria with Ca and Mg. Potassium addition, moisture content, temperature, and equilibration time are some of the more important factors. An additional environmental factor which has evoked much attention recently is contamination of agricultural soils with heavy metals. The effects of heavy metals on physiological interferences to crop growth are generally well known, but little is known relative to their influence on chemical properties of soil-solution-plant relations and, hence, on cation nutrient availability and exchange equilibria.

The objectives of this study were to (1) develop chemical indices for characterizing soil K availability, and (2) determine thermodynamic parameters for evaluating K exchange equilibria with Ca and Mg between soil and solution. Both the ILD technique and K adsorption isotherm method were employed, and heavy metal additions were included as treatments. Soil K availability was characterized chemically by determining (1) activity (conc) of K in soil solution, (2) exchangeable K by NH_4OAc at pH 7.0, (3) K adsorption isotherm, (4) Q/I relations and potassium buffering capacity, (5) potassium nutrient potential, and (6) potassium fractional saturations. Potassium exchange equilibria were evaluated thermodynamically by determining (1) selectivity coefficients and (2) preferential K adsorption isotherm.

LITERATURE REVIEW

Extraction of Soil Solution

Soil solution is the aqueous liquid phase of the soil and its solutes consist of ions dissociated from the surfaces of soil particles and other soluble materials. Because soil solution is the medium in which soil chemical reactions occur and from which plants obtain mineral nutrients, there has been a long-time interest in knowing its chemical composition. Numerous methods to extract soil solution have been proposed based on the principles of suction, pressure, displacement, and centrifuge. However, separating unaltered soil solution from solid-phase soil has been difficult.

The column displacement method (Parker, 1921) has been used successfully for many years (Adams, 1974), but the major disadvantage for this method is that operator skill and experience are required in packing columns. The method works well only on limited ranges of soil textures and moisture contents, and it requires constant attention during solution collection (Adams, et al., 1980).

The suction method has survived primarily in the form of the pressure membrane or pressure plate method (Richards, 1941). The major disadvantages of this method are (1) the pressure membrane or plate effectively removes phosphate from the solution, (2) excess water must be added to the soil-membrane or soil-plate interface so that water films will be contiguous from membrane to soil particles, and (3) high

atmosphere of gas pressure within the chamber will alter CO_2 solubility and, hence, solution pH. Therefore the suction method is not suitable for extraction of the real soil solution. The most successful application of the suction method has been not in collecting soil solution composition data but in defining moisture retention curves for soils at moisture contents between field capacity and permanent wilting percentage (Adams, 1974; Faber and Nelson, 1984).

The suction principle also applies to porous ceramic cup method (Wagner, 1962; Hansen and Harris, 1975) and porous plastic filter method (Hossner and Phillips, 1973) in which ceramic cup or plastic filter are embedded in moist soil to obtain soil solution. Solutions obtained in these methods probably have been altered from the true soil solution by (1) the sieving action of the ceramic clay and filter, (2) the altered gas pressure, (3) sorption of elements, (4) leaching of soil solution, and (5) diffusion (Adams, 1974; Faber and Nelson, 1984).

A successful centrifuge method was developed later (Davies and Davies, 1963) and recent improvements in this method suggest that it can be used with fewer problems than the other methods (Edmunds and Bath, 1976; Gillman, 1976; Mubarak and Olsen, 1976a; Reynolds, 1984). Centrifuge method requires no special skills and is easy to use. It works on all soils, but it is particularly good on coarse-textured soils. It has the additional advantage of being nondestructive on the sample, and the soil can be used subsequently for other studies.

While the centrifuge method offers a method for extracting unaltered bulk solution over a desired range of moisture tensions, this
