## Abstract

Nonnative annual brome invasion is a major problem in many ecosystems throughout the semiarid Intermountain West, decreasing production and biodiversity. Herbicides are the most widely used control technique but can have negative effects on co-occurring species. Graminicides, or grass-specific herbicides, may be able to control annual bromes without harming forbs and shrubs in restoration settings, but limited studies have addressed this potential. This study focused on evaluating the efficacy of glyphosate and four graminicides to control annual bromes, specifically downy brome and Japanese brome. In a green-house, glyphosate and four graminicides (clethodim, sethoxydim, fluzifop-P-butyl, and quizalofop-P-ethyl) were applied at two rates to downy brome plants of different heights (Experiment 1) and to three accessions of downy brome and Japanese brome of one height (Experiment 2). All herbicides reduced downy brome biomass, with most effective control on plants of less than 11 cm and with less than 12 leaves. Overall, quizalofop-P-ethyl and fluzifop-P-butyl treatments were most effective, and glyphosate and sethoxydim treatments least effective. Accessions demonstrated variable response to herbicides: the downy brome accession from the undisturbed site was more susceptible to herbicides than downy brome from the disturbed accession and Japanese brome accessions. These results demonstrate the potential for graminicides to target these annual bromes in ecosystems where they are growing intermixed with desired forbs and shrubs.

### Nomenclature:

Glyphosate; quizalofop-P-ethyl; fluzifop-P-butyl; clethodim; sethoxydim; downy brome, *Bromus tectorum* L.; Japanese brome, *Bromus japonicus* Houtt

### Keywords:

Annual brome control; cheatgrass; restoration; weed management

Downy brome and Japanese brome are two nonnative winter annual grasses that have invaded the western United States, with downy brome present in the cold deserts, western Great Plains, and western forests; and Japanese brome found mainly in the western Great Plains (Germino et al. 2016). These annual grasses can have substantial impacts in croppeds (Blackshaw 1993; Rydrych and Muzik 1968) and rangeland areas (Haferkamp and Heitschmidt 1999; Ogle et al. 2003). Downy brome has been found to reduce winter wheat (*Triticum aestivum* L.) biomass by up to 59% and grain yield by up to 68% (Blackshaw 1993). Japanese brome has been shown to impact grass yield in rangelands; its removal from a western wheatgrass [*Pascopyrum smithii* (Rydb.) Å. Löve] rangeland increased standing crop yield by 220 kg ha<sup>-1</sup> and tillers by 153 m<sup>-2</sup> (Haferkamp and Heitschmidt 1999). Downy brome also impacts ecosystem processes by competing with native grasses (Francis and Pyke 1996; Nasri and Doescher 1995; Vasquez et al. 2009), changing fire regimes (Brooks et al. 2004; Whisenant 1990), altering available nitrogen (Rimer and Evans 2006; Sperry et al. 2006), increasing soil organic carbon storage (Norton et al. 2004; Ogle et al. 2004), and modifying nutrient cycling (Belnap and Phillips 2001; Norton et al. 2004). There are currently no studies assessing these ecological impacts for Japanese brome.

Although there have been attempts to manage downy brome and Japanese brome with prescribed fire, grazing, tillage, and biological control in range- and wildlands (Brooks et al. 2016; Cox and Anderson 2004; DiTomaso et al. 2006; Ehlert et al. 2014; Germino et al. 2016; Harmoney 2007; Lehnhoff et al. 2019; Masters and Sheley 2001; Metier et al. 2018;

54 Monsen et al. 2004; Vermeire et al. 2008; Whitson and Koch 1998),  
 55 herbicides are still the most widespread management tool, though  
 56 they are often used in combination with grazing and seeding in  
 57 rangelands (Kelley et al. 2013; Monaco et al. 2017). Herbicides are  
 58 also the most widely used tool in cropping systems (Radosevich  
 59 et al. 2007). Glyphosate is commonly used to control weedy species  
 60 during the fallow phase in cropping systems and during restoration  
 61 of range- and wildlands. Rangeland field studies reported high  
 62 (Morris et al. 2017) to very high levels of downy brome control  
 63 after one (>97%) (Cox and Anderson 2004; Whitson and Koch  
 64 1998) and three (>92%) consecutive applications (Whitson and  
 65 Koch 1998) of glyphosate. In the greenhouse, Park and Mallory-  
 66 Smith (2004) found an average of 85% reduction of downy brome  
 67 biomass when treated with glyphosate compared with an untreated  
 68 control. Less is known about the efficacy of glyphosate on Japanese  
 69 brome, though Waller and Schmidt (1983) reported glyphosate  
 70 provided good control of Japanese brome. However, because glyph-  
 71 osate is a broad-spectrum herbicide, it is not suitable for all situations  
 72 (Baker et al. 2009; Morris et al. 2009; Owen et al. 2011).

73 Graminicides are grass-specific POST herbicides that inhibit  
 74 acetyl-CoA carboxylase (ACCase) enzyme, specifically the pro-  
 75 duction of phospholipids required for cell membrane production  
 76 (Délye et al. 2002). Graminicides are used in annual cropping  
 77 systems (Foy and Witt 1992; Marquardt and Johnson 2013),  
 78 and usage will likely increase with the release of wheat varieties  
 79 with ACCase herbicide tolerance traits where quizalofop-P-ethyl  
 80 is recommended as the herbicide (e.g., CoAXium<sup>®</sup> wheat,  
 81 CoAXium Wheat Production System, Co.). They are also widely  
 82 used in forestry (Clay et al. 2006), but they are used less in  
 83 rangeland and restoration scenarios (James et al. 2013). These  
 84 herbicides, including clethodim, sethoxydim, fluzifop-P-butyl,  
 85 and quizalofop-P-ethyl (hereafter fluzifop and quizalofop),  
 86 are phytotoxic to grasses, but unlike glyphosate they do not  
 87 affect forbs or shrubs (Kukorelli et al. 2013). For this reason,  
 88 they may be particularly useful at sites dominated by annual  
 89 grasses, where few perennial grasses and some desired forbs  
 90 and shrubs exist.

91 Research on the effect of these graminicides on downy  
 92 brome and Japanese brome is limited, though what exists is  
 93 encouraging. Dense downy brome cover was reduced over a  
 94 5-yr period with sethoxydim (~70%), fluzifop (95%), and  
 95 quizalofop (99%) applied at label rates in a field study at  
 96 Oregon State University (Brewster and Spinney 1989).  
 97 Similarly, high rates of biomass reduction were observed in a  
 98 greenhouse study for sethoxydim (85%), clethodim, fluzifop,  
 99 and quizalofop (all >98%) when applied at the recommended  
 100 herbicide label rates (Ball et al. 2007).

101 The goal of this study was to build on previous work and  
 102 examine the efficacy of glyphosate and graminicides to control  
 103 downy brome and Japanese brome. Specifically, we evaluated  
 104 the effect of herbicide type, application rate, and plant size (target  
 105 plant height and leaf number at time of application) on different  
 106 downy brome and Japanese brome accessions in a controlled  
 107 setting. Our first objective was to evaluate the efficacy of glyphosate  
 108 and four graminicides (clethodim, sethoxydim, fluzifop, and  
 109 quizalofop) on downy brome biomass at high and low label-  
 110 recommended application rates of each herbicide when applied  
 111 across five different plant heights using one downy brome accession.  
 112 Our second objective was to compare the efficacy of glyphosate and  
 113 the same four graminicides at high and low label-recommended  
 114 application rates across three accessions of both downy brome  
 115 and Japanese brome, applied at one plant height.

## Materials and Methods

### *Herbicide Type and Rate Applied to Downy Brome of Different Heights (Experiment 1)*

The efficacy of downy brome control was evaluated for four  
 graminicides (clethodim, sethoxydim, fluzifop, and quizalofop)  
 and glyphosate. All herbicides were applied at two rates (low  
 and high label-recommended rates for downy brome [and  
 Japanese brome where stated]; Table 1) to plants that had reached  
 five predefined aboveground heights (5, 8.5, 11, 15.5, and 17 cm).

The experiment was established as a randomized complete  
 block design with 11 treatments (10 herbicides and an untreated  
 control) by 5 heights by 7 replicates (385 experimental units).  
 The experimental unit was 1 downy brome seedling per pot.  
 The experiment was performed twice (Trial 1: November 2014  
 through May 2015; and Trial 2: November 2015 through May  
 2016) in a greenhouse with a 16-h photoperiod at  $22 \pm 4^\circ\text{C}$  daytime  
 temperatures and  $17 \pm 6^\circ\text{C}$  nighttime temperatures. At 30 d after  
 seeding, the plants assigned to the three tallest height groups were  
 transferred to a cold chamber ( $4^\circ\text{C}$ , 12-h photoperiod) for 6 wk to  
 vernalize and were then returned to the greenhouse. Plants in  
 the two shorter height groups did not receive the vernalization  
 treatment, because at 30 d they were already close to their desired  
 height for herbicide application. Plant height was determined using  
 the average height of three randomly selected extended leaves.  
 Pots were watered equally and as needed. Plants were sprayed  
 when the average replicate height reached its predefined target  
 (5, 8.5, 11, 15.5, and 17 cm). The number of leaves per plant  
 was recorded at the time of spray application. For all herbicide  
 treatments, a nonionic surfactant (X-77 Spreader, Loveland  
 Products, 3005 Rocky Mountain Ave, Loveland, CO 80538) was  
 added at a rate of 0.25% v/v. Herbicides were applied using a mov-  
 ing nozzle sprayer (DeVries Manufacturing, 86956 State Highway  
 251, Hollandale, MN 56045) calibrated to deliver  $94\text{ L ha}^{-1}$  of spray  
 solution (i.e., water plus herbicide plus surfactant) at 276 kPa.  
 Plants were harvested at the root crown at 45 d after herbicide  
 application; all remaining plant tissue was dried at  $40^\circ\text{C}$  for  
 72 h and weighed.

### *Herbicide Type and Rate Applied to Three Downy Brome and Japanese Brome Accessions (Experiment 2)*

The efficacy of the same four graminicides and glyphosate, applied  
 at two application rates, was assessed on three downy brome and  
 Japanese brome accessions. Seed accessions of both species were col-  
 lected from three grassland locations to determine whether there  
 were site-specific differences in response to herbicides. Downy brome  
 and Japanese brome seeds were collected from “disturbed” restora-  
 tion sites on Decker ( $45.056780^\circ\text{N}$ ,  $106.840467^\circ\text{W}$ ) and Spring Creek  
 ( $45.139351^\circ\text{N}$ ,  $106.921612^\circ\text{W}$ ) coal mines, north of Decker, MT,  
 in the Powder River Basin. Nomenclature is based on Lesica  
 (2012). The remaining downy brome site was in rangeland at the  
 Montana State University Red Bluff Agricultural Research Ranch  
 in Norris, MT ( $45^\circ52'\text{N}$ ,  $111^\circ68'\text{W}$ ; also used in Experiment 1),  
 and the Japanese brome site was Burke Park in Bozeman, MT  
 ( $45^\circ67'\text{N}$ ,  $111^\circ03'\text{W}$ ). These two sites are hereafter referred to as  
 “undisturbed.” This experiment was conducted over a 7-mo period  
 (November 2015 through May 2016) in a greenhouse with the same  
 temperature and light and watering conditions as Experiment 1.

The experiment was designed as a randomized complete block  
 design: 11 treatments (10 herbicides and an untreated control) by  
 2 species by 3 accessions by 7 replicates (462 experimental units).

**Table 1.** Herbicide common and trade names and the recommended low and high rates used for our downy brome and Japanese brome experiments.

Herbicide	Trade Name	Low rate	High rate
		kg ai ha <sup>-1</sup>	
Sethoxydim	Poast® Plus <sup>a</sup>	0.210	0.315
Clethodim	Select Max <sup>®b</sup>	0.076	0.136
Fluazifop	Fusilade® II <sup>c</sup>	0.280	0.420
Quizalofop	Assure® II <sup>d</sup>	0.077	0.092
Glyphosate	Roundup Ultra <sup>e</sup>	0.420	0.560

175 For this experiment, we used one plant height (11 cm) as our target  
176 plant size. After 30 d, seedlings were placed in the cold chamber  
177 (4°C, 12-h photoperiod) to vernalize for 6 wk and were then  
178 returned to the greenhouse. When the average height of the  
179 plants within a replicate reached 11 cm, the same herbicide  
180 treatments were applied using the same procedures as described  
181 for Experiment 1. Similarly, the number of leaves at time of  
182 herbicide application was recorded. Again, aboveground biomass  
183 was harvested at 45 d after herbicide application, and the resulting  
184 plant biomass was harvested and dried.

## 185 Data Analysis

186 Data were analyzed with linear mixed-effects models using the  
187 LMERTEST and LME4 (Bates et al. 2015) packages. Least-squares  
188 means and Tukey pairwise comparisons were evaluated using  
189 the LSMEANS (Lenth 2016) package. Data analysis was performed  
190 using R v. 3.3.2 (R Core Team 2016). The most parsimonious  
191 model was selected using Akaike information criterion (AIC) with  
192 a decrease in AIC score of 2 being considered a better fit. In all  
193 models, the biomass response variable was natural log (ln) trans-  
194 formed to satisfy model assumptions.

195 For Experiment 1, a linear mixed-effects model was created in  
196 which the response variable was plant biomass (ln) at time of  
197 harvest for each replicate. Initially, a full model was run with fixed  
198 effects for treatment (all herbicide and rate combinations), height  
199 at time of application (5, 8.5, 11, 15.5, or 17 cm), and trial (1 and 2),  
200 along with the interactions among treatment and height, trial and  
201 height, and treatment, trial, and height, as well as a random effect  
202 for replicate. Individual models were then created for each plant  
203 height group to better elucidate the efficacy of herbicide treat-  
204 ments. For 5-cm, 8.5-cm, and 17-cm plant heights, fixed effects  
205 were herbicide, trial, and the interaction between herbicide and  
206 trial. (Data from the 5-cm plant height treated with the clethodim  
207 low rate during Trial 2 in Experiment 1 were excluded due to a  
208 problem with the spray chamber during application.) For the  
209 11-cm and 15.5-cm plants, herbicide and trial were included as  
210 fixed effects, and no interaction term was necessary. In all models,  
211 a random effect was included for replicate.

212 As herbicide application timing is also often based on number  
213 of leaves, we developed a second model in which number of leaves,  
214 rather than height, was used as an explanatory variable. The most  
215 parsimonious linear mixed-effects model had plant biomass (ln)  
216 at time of harvest as the response variable with fixed effects for

treatment (all herbicide and rate combinations), trial (1 and 2),  
217 and number of leaves (ln) at time of application, along with the  
218 interactions between treatment and number of leaves, trial and  
219 number of leaves, and a random effect for replicate.  
220

221 Similar models were created for plant biomass (ln) at time of  
222 harvest for Experiment 2. Fixed effects included herbicide treat-  
223 ment (all herbicide and rate combinations), accession (Decker,  
224 Spring Creek, or undisturbed), and species (Japanese brome or  
225 downy brome), as well as the interaction between herbicide and  
226 species. There was no difference between the Spring Creek and  
227 Decker mine accessions ( $P = 0.3393$ ), so they were combined  
228 in the final analysis and are hereafter referred to as “disturbed.”  
229 A random effect was included for replicate.

## Results and Discussion

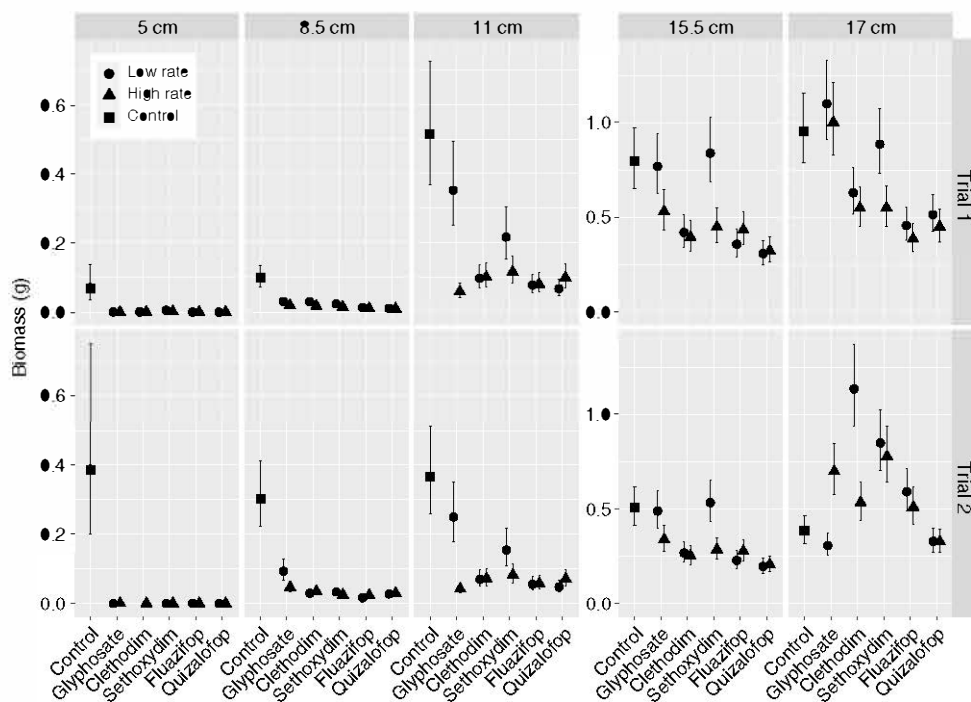

230  
231 Our results demonstrate that fluazifop, quizalofop, clethodim,  
232 sethoxydim, and glyphosate can all reduce downy brome and  
233 Japanese brome biomass, especially when applied shortly after  
234 germination—with a tendency for fluazifop and quizalofop to

235 be most effective. Our study demonstrates that targeting smaller  
236 plants, specifically plants 11 cm or smaller with less than 12 leaves,  
237 provides more reliable results. In Experiment 1, plants that were  
238 shorter ( $\leq 11$  cm) with fewer leaves ( $\leq 12$  leaves) at time of herbi-  
239 cide application were most affected, with biomass reduced by more  
240 than 50% of the control for all but the low glyphosate treatment  
241 at 11 cm. However, little or no reduction in biomass was observed  
242 when herbicides were applied at the 17-cm height. A similar  
243 pattern was observed across herbicides for Experiment 2, where  
244 treatments were only applied to 11-cm plants: quizalofop and flua-  
245 zifop were again the most effective, and the low rate of glyphosate  
246 was the least effective at reducing biomass at 45 d after treatment.

### The Importance of Plant Size

247  
248 Efficacy of different herbicides applied at two rates was assessed  
249 across growth stages (height and number of leaves). The main  
250 effect of trial was significant for all downy brome height groups.  
251 For the shortest height groups (5 cm and 8.5 cm), there was greater  
252 biomass reduction in the first than the second trial (Supplementary  
253 Tables S1 and S2), with the opposite pattern for the taller groups  
254 (Figure 1; Supplementary Tables S4 and S5). All herbicide treat-  
255 ments reduced downy brome biomass when applied to the two  
256 shortest groups of plants (5 cm and 8.5 cm) compared with the  
257 control (Supplementary Tables S1 and S2, respectively). This  
258 was also true for 11-cm plants, with the exception of the low rate  
259 of glyphosate (Supplementary Table S3), and for 15.5-cm plants  
260 with the low rate of glyphosate and sethoxydim (Supplementary  
261 Table S4). The tallest plants (17 cm) showed less response, with  
262 neither rate of glyphosate nor a low rate of sethoxydim reducing  
263 plant biomass compared with the control in the first trial and only  
264 the low rate of glyphosate reducing biomass in the second trial  
265 (Supplementary Table S5).

266 When the data from Experiment 1 were analyzed using number  
267 of leaves at time of spraying (continuous variable) instead of height  
268 at time of spraying, the results yielded similar patterns (Figure 2).  
269 As the number of leaves at time of spraying increased, the efficacy  
270 of all herbicide treatments decreased (Figure 2; Supplementary  
271 Table S6;  $P = 0.0018$ ), and generally the herbicides worked best  
272 on plants with fewer than 12 leaves (ln 2.48). There was little differ-  
273 ence among herbicide treatments applied at the high rate, but

**Figure 1.** Effect of different herbicides and application rates on individual downy brome biomass (g) for plants treated at different growth stages (height) in the two trials of Experiment 1. Mean plant biomass (symbols) and SE (vertical line) of the individual plants within a replicate are presented, using least-squares means (backtransformed natural log values) from the mixed-effects model. See Supplementary Tables S1–S5 for further statistical comparison and text for pairwise comparisons.

**Figure 2.** Effect of different herbicides and application rates on individual downy brome biomass (g) for plants treated at different growth stages (number of leaves) in the two trials of Experiment 1. Points represent individual plants. See Supplementary Table S6 for further statistical comparison.

274 fluazifop and quizalofop were more effective at reducing plant bio-  
275 mass at low rates (Figure 2; pairwise comparisons not shown).

276 Not all studies provide information on plant height or number  
277 of leaves at the time of application, making comparisons between

our work and that of others difficult. However, studies on a  
278 frequently used herbicide in rangeland found no difference in  
279 downy brome control when imazapic (acetohydroxyacid synthase  
280 branched-chain amino acid inhibitor) was applied to plants with  
281

282 2 to 4 leaves compared with plants with 5 to 10 leaves, in agreement  
 283 with our results. In contrast, Mangold et al. (2013) found that  
 284 downy brome control increased when imazapic was applied to  
 285 plants at the 1- to 2-leaf stage compared with the 3- to 4-leaf  
 286 stage, a finer differentiation than we observed. However, all these  
 287 studies demonstrate that brome control varies on a finer scale  
 288 (i.e., 2.5-cm-height intervals) than is often recommended on  
 289 herbicide labels. While logistical constraints of large-scale herbi-  
 290 cide applications (timing of precipitation, weather patterns, plant  
 291 growth patterns, access, etc.) often hamper timely application, both  
 292 plant height and number of leaves are simple to assess in the field,  
 293 and this practice should be adhered to more carefully.

#### 294 Efficacy of Herbicides and Rates

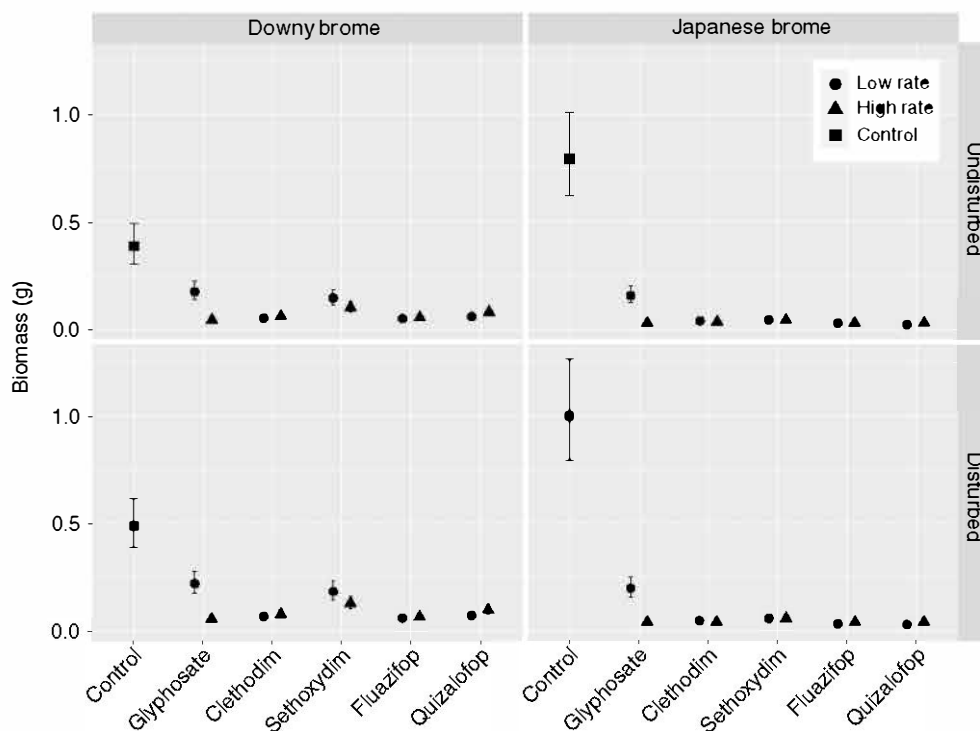

295 Overall, glyphosate was not as effective at reducing biomass as the  
 296 graminicides, with the low rate of glyphosate often performing  
 297 worst. That said, for the shortest plants (5 cm), there were no  
 298 biomass differences between low and high rates of any herbicide  
 299 treatments, in either trial (Figure 1). However, for the middle  
 300 height groups, the low rate of glyphosate performed less well.  
 301 For the 8.5-cm height, in both trials the glyphosate applied  
 302 at low rate resulted in higher biomass than both fluzifop  
 303 (Trial 1 low,  $P=0.0496$ ; Trial 2 low,  $P<0.0001$ ; Trial 1 high,  
 304  $P=0.0028$ ; Trial 2 high,  $P<0.0001$ ) and quizalofop (Trial 1  
 305 low,  $P=0.0044$ ; Trial 2 low,  $P<0.0001$ ; Trial 2 high,  
 306  $P=0.0008$ ; Trial 2 high,  $P=0.0002$ ) treatment rates; and in the  
 307 second trial only, the glyphosate low rate resulted in higher  
 308 biomass than both rates of sethoxydim (low,  $P=0.0016$ ; high,  
 309  $P<0.0001$ ) and clethodim (low,  $P=0.0002$ ; high,  $P=0.0029$ ).  
 310 For the 11-cm height, the low rate of glyphosate had higher  
 311 biomass than both rates of fluzifop, quizalofop, and clethodim  
 312 ( $P<0.0001$  for all), as well as the high rates of sethoxydim  
 313 ( $P=0.0006$ ) and glyphosate ( $P<0.0001$ ). There was a similar  
 314 trend for the 15.5-cm height: the low rate of glyphosate had higher  
 315 biomass than both rates of fluzifop (low,  $P<0.0001$ ; high,  
 316  $P=0.0102$ ), quizalofop ( $P<0.0001$  for both) and clethodim  
 317 (low,  $P=0.0044$ ; high,  $P=0.0007$ ), and the sethoxydim high rate  
 318 ( $P=0.0235$ ). For the 17-cm height, trial was again significant, and  
 319 there was an interaction with herbicide. In the first trial, the glyph-  
 320 osate low rate had higher biomass than both rates of fluzifop and  
 321 quizalofop ( $P<0.0001$  for all) and clethodim (low,  $P=0.0121$ ;  
 322 high,  $P=0.0002$ ) and the sethoxydim high rate ( $P=0.0003$ ).  
 323 However, in the second trial, the glyphosate low rate had lower  
 324 biomass than both rates of fluzifop (low,  $P=0.0008$ ; high,  
 325  $P=0.0414$ ), clethodim (low,  $P<0.0001$ ; high,  $P=0.0131$ ), and  
 326 sethoxydim ( $P<0.0001$  for both) and the glyphosate high rate  
 327 ( $P<0.0001$ ).

328 All graminicides performed well, with fluzifop and quizalofop  
 329 outperforming clethodim and sethoxydim in all but the shortest  
 330 group (Figure 1). Response to fluzifop and quizalofop was similar,  
 331 with low rates generally performing as well or better than the  
 332 high rates. In the first trial for the 8.5-cm height, the low rate of  
 333 quizalofop ( $P=0.0062$ ) and fluzifop ( $P=0.004$ ) resulted in  
 334 less biomass than the clethodim low rate, and the high rate  
 335 of quizalofop had less biomass than the low rates of clethodim  
 336 ( $P=0.0012$ ) and sethoxydim ( $P=0.0309$ ): there were no differ-  
 337 ences among graminicides in Trial 2. For the 11-cm height in both  
 338 trials, the low rate of quizalofop ( $P=0.0002$ ) and fluzifop  
 339 ( $P=0.0026$ ) and high rate of fluzifop ( $P=0.0048$ ) had less  
 340 biomass than the sethoxydim low rate. For the 15.5-cm height  
 341 in both trials, both rates of fluzifop (low,  $P<0.0001$ ; high,

$P=0.0009$ ) and quizalofop ( $P<0.0001$  for both) had less biomass  
 342 than the sethoxydim low treatment. Similarly, for the 17-cm height  
 343 in Trial 1, both rates of fluzifop (low,  $P=0.0007$ ; high,  $P<0.0001$ )  
 344 and quizalofop (low,  $P=0.0177$ ; high,  $P=0.0004$ )  
 345 had less biomass than the sethoxydim low rate. In the second trial,  
 346 the fluzifop high rate ( $P=0.0365$ ) had less biomass than the  
 347 sethoxydim low rate, and both quizalofop rates had less biomass  
 348 than both sethoxydim rates ( $P<0.0001$  for all). The only differ-  
 349 ence between fluzifop and quizalofop was in the 17-cm height  
 350 group in Trial 2, where both quizalofop rates (low,  $P=0.0058$ ;  
 351 high,  $P=0.0046$ ) outperformed the fluzifop low rate.

352 In our second experiment that evaluated the efficacy of  
 353 herbicide type and rate on different downy and Japanese brome  
 354 accessions, we observed the same patterns at the same growth  
 355 stage(s) as in Experiment 1. However, herbicides caused notably  
 356 greater biomass reduction to Japanese brome than downy brome  
 357 (Figure 3; Supplementary Table S7;  $P<0.0001$ ). Overall, the  
 358 graminicides performed better than the low rate of glyphosate,  
 359 which was the least effective at controlling both downy and  
 360 Japanese brome (Figure 3). The low rate of glyphosate resulted  
 361 in greater downy brome biomass than both rates of fluzifop  
 362 ( $P<0.0001$  for both), quizalofop (low,  $P<0.0001$ ; high,  
 363  $P<0.0025$ ) and clethodim ( $P<0.0001$  for both), as well as the  
 364 glyphosate high rate ( $P<0.0001$ ). The most effective herbicides  
 365 were fluzifop and quizalofop, with low rates performing well,  
 366 again similar to Experiment 1. Both fluzifop rates and the  
 367 quizalofop low rate ( $P<0.0001$  for all) had less biomass than the  
 368 sethoxydim low rate; and the fluzifop low treatment had less  
 369 biomass than the sethoxydim high treatment ( $P=0.0168$ ). Low-rate  
 370 application of sethoxydim was generally the least effective of the  
 371 graminicides and produced greater biomass than both rates of  
 372 clethodim (low,  $P<0.0001$ ; high,  $P=0.0008$ ).

373 In summary, application rate did not affect the efficacy of  
 374 graminicides when applied to smaller plants ( $\leq 11$  cm,  $\leq 12$  leaves),  
 375 with low rates often performing better, but both application rates  
 376 reduced plant biomass by at least 50% compared with the control.  
 377 However, for glyphosate, application rate did matter. Glyphosate  
 378 applied at the high rate was more effective than the low rate when  
 379 applied to  $<11$ -cm plants in Experiments 1 and 2. Thus, for glyph-  
 380 osate, the high application rate was necessary to ensure adequate  
 381 control; this will likely be especially important in a field setting,  
 382 where target plant heights could vary. Park and Mallory-Smith  
 383 (2004) applied glyphosate at a rate of  $0.420 \text{ kg ai ha}^{-1}$  to downy  
 384 brome plants in the 3- to 4-leaf stage and found an average of  
 385 85% control. In our study, this same treatment (8.5-cm-height  
 386 group treated with our low glyphosate rate) only provided an  
 387 average of 68% control of downy brome. In a Wyoming field  
 388 experiment, Whitson and Koch (1998) applied glyphosate to  
 389 downy brome plants at the 2- to 8-leaf stage at 0.42, 0.55, 0.69,  
 390 and  $0.83 \text{ kg ai ha}^{-1}$  and achieved  $>99\%$  decrease in live canopy  
 391 cover in all treatments. This is far greater control than we achieved  
 392 with our glyphosate treatments in our comparable (11-cm) group.  
 393 It has been shown that higher rates of imazapic can increase the  
 394 effectiveness of downy brome control (Morris et al. 2009), but  
 395 broad-spectrum herbicides like glyphosate and imazapic can also  
 396 damage desired species (Kyser et al. 2013). Because graminicides  
 397 are grass specific, using a higher rate to control bromes should  
 398 not increase the damage to non-target shrub and broadleaf species  
 399 (Kukorelli et al. 2013), but our results suggest that the low label  
 400 rate of fluzifop or quizalofop should provide good control, as  
 401 well as provide a good alternative to broad-spectrum herbicides  
 402 in restoration scenarios.

**Figure 3.** Effect of different herbicides and application rates on individual plant biomass (g) for undisturbed and disturbed downy brome (left) and Japanese brome (right) accessions treated at one growth stage (11-cm mean plant height) for Experiment 2. Mean plant biomass (symbols) and SE (vertical line) of the individual plants within a replicate are presented, using least-squares means (back-transformed natural log values) from the mixed-effects model. See Supplementary Table S7 for statistical comparison and text for pairwise comparisons.

404 All herbicides were more effective at reducing Japanese brome  
 405 biomass compared with downy brome. Biomass of untreated  
 406 (control) Japanese brome plants was greater than biomass of  
 407 untreated downy brome plants, but in contrast, Japanese brome  
 408 plants treated with herbicides all had lower biomass than their  
 409 downy brome counterparts that received the same application  
 410 (Figure 3; Supplementary Table S7). Furthermore, all of the grami-  
 411 nicides reduced Japanese brome accessions in comparison with the  
 412 low rate of glyphosate ( $P < 0.0001$  for all treatments). Other studies  
 413 have found that glyphosate is effective at reducing downy brome  
 414 biomass (Cox and Anderson 2004; Morris et al. 2017; Park  
 415 and Mallory-Smith 2004; Whiston and Koch 1998), and in the only  
 416 study to test effectiveness on Japanese brome, Waller and Schmidt  
 417 (1983) stated that it provided excellent control of Japanese brome  
 418 in a Nebraska tallgrass prairie, though no data were reported. This  
 419 also agrees with our findings, but for both Japanese and downy  
 420 brome, the low glyphosate rate performed significantly worse than  
 421 the high rate, where the biomass was 457% and 395% greater,  
 422 respectively. There is limited information addressing graminicides'  
 423 ability to control downy brome (Ball et al. 2007; Brewster and  
 424 Spinney 1989), but in the few studies that do, graminicides  
 425 provided good control. Additionally, our study agrees with Ball  
 426 et al. (2007), who found that quizalofop and fluazifop are generally  
 427 the most effective, and sethoxydim the least effective of these  
 428 herbicides. Our study is the first we know of that tests the efficacy  
 429 of these graminicides on Japanese brome.

#### 430 Differences in Populations

431 Biomass of downy and Japanese brome accessions from disturbed  
 432 sites was greater than for the undisturbed downy brome across all

herbicide treatments (Figure 3; Supplementary Table S7; 433  
 $P < 0.0001$ ); however, pairwise comparisons showed there was 434  
 no difference between the disturbed and undisturbed Japanese 435  
 brome accessions. There is evidence to suggest that plant 436  
 characteristics such as cold tolerance (Bykova and Sage 2012), 437  
 germination success (Hardegee et al. 2013), and vernalization 438  
 requirements (Lawrence et al. 2018) can vary across downy brome 439  
 accession. Additionally, some downy brome accessions have devel- 440  
 oped resistance to both acetolactate synthase (ALS) inhibitors 441  
 (Mueller-Warrant et al. 1999; Park and Mallory-Smith 2004) 442  
 and graminicides (Ball et al. 2007; Park and Mallory-Smith 443  
 2004). While we found differences in herbicide control among 444  
 accessions, geography as well as disturbance history may be a 445  
 factor. The disturbed sites (Spring Creek and Decker mine) are 446  
 located within 25 km of one another, so they are more likely to 447  
 be genetically similar to each other, and this could be why there 448  
 was no difference between them. The undisturbed sites have 449  
 received little if any herbicide management and low disturbance 450  
 (e.g., grazing) pressure, but they are also geographically distant 451  
 from the disturbed sites. 452

#### 453 Conclusion

Herbicide control of annual bromes is important, as these two 454  
 species have invaded large areas of the western United States 455  
 (Chambers et al. 2007; Duncan et al. 2004; Haferkamp et al. 456  
 1992; Knapp 1996; Whisenant 1990), their ranges are expanding 457  
 (Bradley 2009; Bradley et al. 2016), and they are negatively impacting 458  
 many different ecosystems (Blackshaw 1993; Haferkamp and 459  
 Heitschmidt 1999; Gle et al. 2003; Rydrych and Muzik 1968). 460  
 Our results demonstrate that graminicides, specifically fluazifop 461

462 and quizalofop, can be used to successfully control annual bromes.  
 463 In wheat-dominated agroecosystems of the northwestern United  
 464 States there are more frequent reports of downy brome populations  
 465 resistant to ALS herbicides (Barroso and Gourlie 2019), and the  
 466 introduction of ACCase-resistant wheat and the associated applica-  
 467 tion of quizalofop will help to reduce these populations. In highly  
 468 disturbed rangeland restoration ecosystems, these graminicides  
 469 could provide a useful tool and improve control efficacy, but evalu-  
 470 ation under field conditions where desired species are present is  
 471 required before recommendations can be made.
