21 **ABSTRACT**

22 **Purpose of Review**

23 Osteocytes directly modify the bone surrounding the expansive lacunar-canalicular system (LCS) through  
24 both resorption and deposition. The existence of this phenomenon is now widely accepted, but is  
25 referred to as “osteocyte osteolysis,” “LCS remodeling,” and “perilacunar remodeling,” among other  
26 names. The uncertainty in naming this physiological process reflects the many persistent questions  
27 about why and how osteocytes interact with local bone matrix. The goal of this review is to examine the  
28 purpose and nature of LCS remodeling and its impacts on multiscale bone quality.

29  
30 **Recent Findings**

31 While LCS remodeling is clearly important for systemic calcium mobilization, this process may have  
32 additional potential drivers and may impact the ability of bone to resist fracture. There is abundant  
33 evidence that the osteocyte can resorb and replace bone mineral and does so outside of extreme  
34 challenges to mineral homeostasis. The impacts of the osteocyte on organic matrix are less certain,  
35 especially regarding whether osteocytes produce osteoid. Though multiple lines of evidence point  
36 towards osteocyte production of organic matrix, definitive work is needed. Recent high-resolution  
37 imaging studies demonstrate that LCS remodeling influences local material properties. The role of LCS  
38 remodeling in the maintenance and deterioration of bone matrix quality in aging and disease are active  
39 areas of research.

40 **Summary**

41 In this review, we highlight current progress in understanding why and how the osteocyte removes and  
42 replaces bone tissue and the consequences of these activities to bone quality. We posit that answering  
43 these questions is essential for evaluating whether, how, when, and why LCS remodeling may be  
44 manipulated for therapeutic benefit in managing bone fragility.

48

49

## 50 1. Introduction

51 Osteocytes perform numerous functions, from coordinating osteoblast/osteoclast remodeling  
52 and mechanosensing (1–3), to regulating mineral homeostasis (4–6), communicating with organs far  
53 from bone (7–9) and directly remodeling the extracellular matrix of bone (10–12). Osteocytes are  
54 terminally differentiated osteoblasts that reside in lacunae, which are interconnected by small channels  
55 called canaliculi (**Figure 1A**)(1,13). Osteocytes are by far the most abundant cells in the skeleton (>90%)  
56 and can survive decades (1). Osteocytes coordinate bone resorption and bone formation by signaling  
57 that directs the recruitment, proliferation, and differentiation of both osteoclasts and osteoblasts (1–3).  
58 In addition, osteocyte apoptosis in response to fatigue microdamage triggers targeted remodeling to  
59 remove and replace the damaged matrix (14,15). Osteocytes also directly modify the bone surrounding  
60 their lacunar-canalicular system (LCS), though many questions persist about the reasons for this process  
61 and its impacts on bone tissue structure, function, health, and disease (1,4,11). Here, we provide a brief  
62 review of our current understanding of the purpose, the means, and the consequences of LCS  
63 remodeling by osteocytes.

64 Osteocyte osteolysis, the enlargement of osteocyte lacunae and their canaliculi, has been  
65 discussed in the literature for at least 60 years (16,17). The earliest reports were of perilacunar  
66 expansion in chicks fed low calcium diet or administered parathyroid hormone (PTH)(16,17). Osteocytic  
67 osteolysis was the topic of considerable research interest until Parfitt discounted this process and its  
68 study fell out of favor. Parfitt reasoned against osteocyte osteolysis because of technical limitations with  
69 available approaches and because the idea had been presented together with bone flow theory, which  
70 was refuted (18). While several papers over the next decades reported osteocytic bone resorption or  
71 deposition (19–25), more recent work convincingly demonstrated that osteocytes indeed remove and  
72 replace bone mineral in lactating mice (4,26). Since then, advances in imaging and study design reveal  
73 that osteocytes not only remove and replace bone mineral in the context of extreme challenges to  
74 mineral homeostasis, but also perform these activities under normal conditions (1,3,11,27). This direct  
75 matrix-altering osteocytic activity is currently referred to by many names, including osteocyte osteolysis,  
76 perilacunar remodeling, perilacunar-canalicular remodeling, lacunar-canalicular network remodeling,  
77 and lacunar-canalicular system (LCS) remodeling (11,27). We refer to the process as “LCS remodeling” in  
78 this review, though, as we discuss, the word ‘remodeling’ carries specific historical connotations in the  
79 field of bone and mineral metabolism and the naming of this physiological process will likely require re-  
80 visitation as our understanding of the purposes, means, and consequences of this process matures (28–  
81 30).

82 The general purposes of LCS remodeling remain unresolved. Osteocytic osteolysis is clearly  
83 important for the systemic mobilization of calcium (4,6,31–35). LCS network geometries change with  
84 aging, disuse, osteoarthritis, and some therapies against metabolic bone disease, which implies that LCS  
85 remodeling is also dysregulated in these conditions (11,36–43). For these reasons, LCS remodeling is  
86 under consideration as a potential mechanism to modulate osteocyte mechanosensitivity or promote  
87 bone tissue fracture resistance. Whether these impacts are achieved and, if so, whether they are  
88 specifically directed by the osteocyte or secondary to calcium mobilization are unresolved. Here, we  
89 summarize the known and proposed purposes of LCS remodeling and their potential impacts on the  
90 skeleton.

91 Many fundamental questions exist about what components of the bone mineral-organic  
92 composite osteocytes can resorb and rebuild. The greatest certainty is that osteocytes can readily  
93 demineralize and later remineralize bone, although many questions remain about the location, spatial  
94 extent, timescales, and impacts of these processes. There are even more questions about whether and  
95 how the osteocyte removes and replaces extracellular matrix (ECM), including collagen and

96 noncollagenous proteins. These impacts to LCS bone mineral and matrix have the potential to influence  
97 bone quality from the scale of tissue toughening mechanisms to whole bone fracture resistance.

98 In this review, we highlight the current progress in understanding the purpose or purposes of  
99 LCS remodeling and its consequences to bone mineral, matrix, and multiscale bone quality. We also  
100 review key challenges and new approaches for surmounting long-standing questions about the  
101 osteocyte and its many possible impacts.

102

### 103 **1. Purpose of osteocytic lacunar-canalicular system (LCS) remodeling**

104 LCS remodeling is most prominently observed during systemic mobilization of calcium for  
105 reproductive purposes (4,5,10,35,44). Osteocytes actively resorb both perilacunar and pericanalicular  
106 matrix to meet the demands of milk production in mammals (4). Osteocytic bone resorption is a faster  
107 strategy for mobilizing calcium than recruiting and differentiating osteoclasts and occurs over a much  
108 larger surface area. To wit, the LCS surface is several orders of magnitude greater than the surface along  
109 Haversian systems available to osteoclasts and osteoblasts (26). Interestingly, canalicular width is also  
110 increased soon after fracture at non-fractured skeletal sites in mice, indicating a potential role of LCS  
111 remodeling in systemic calcium mobilization to assist the formation of a fracture callous (45). Following  
112 the removal of resorption pressure (e.g., cessation of either lactation or eggshell production), mineral is  
113 re-deposited, enabling peri-osteocytic matrix homeostasis (4,6,10,32). We will discuss existing data on  
114 the nature of the re-deposited matrix below, but whether matrix re-deposition is actively coupled or  
115 merely passive homeostasis secondary to lifting of the resorption pressure remains unknown.

116 PTH is a ubiquitous inducer of LCS remodeling (46). Both lactation and egg production elevate  
117 PTH and PTHrP in the maternal circulation to induce osteocyte osteolysis (47). In mice, mammary gland-  
118 specific deletion of PTHrP abrogates lactation-induced LCS remodeling (48). Exercise-induced LCS  
119 resorption is also mediated by PTH signaling (34). Continuous PTH signaling promotes osteocytic  
120 osteolysis by inducing expression of proton pumps, such as ATPase H<sup>+</sup> Transporting V0 Subunit D2  
121 (ATP6V0D2), which acidify and demineralize bone matrix and matrix-degrading enzymes including  
122 cathepsins and matrix metalloproteinases that degrade the organic matrix (4,35,49). PTH signaling is  
123 largely systemic, but LCS remodeling can also be regulated locally via osteocytic TGF- $\beta$  signaling.  
124 Deletion of the TGF- $\beta$  receptor from osteocytes impairs LCS remodeling, reducing osteocytic expression  
125 of both proton pumps and matrix degrading enzymes (50). We found that osteocyte-conditional  
126 deletion of the mechanosensitive transcriptional regulators, Yes-associated protein (YAP) and  
127 Transcriptional co-activator with PDZ-binding motif (TAZ) similarly disrupted LCS remodeling (51).  
128 Together, these observations suggest that despite diverse signals from both systemic and local factors,  
129 shared mechanisms mediate osteocytic signaling for both mechanotransduction and LCS remodeling.

130 LCS remodeling may have developmental origins. In canalicular network development,  
131 osteocytes actively arrange collagen and excavate the matrix to form the porous LCS. There is  
132 compelling evidence that disruption of osteocyte LCS development can be rescued by postnatal  
133 activation of LCS remodeling (52). Wang and coauthors showed that osteocyte expression of Osterix  
134 (*Sp7*) is required for proper dendrite formation and canalicular network development (52). Remarkably,  
135 they found that both the dendrites and canalicular networks could be rescued within three weeks after  
136 an adenoviral gene-therapy to express the Osterix target gene, Osteocrin, injected at the time of  
137 weaning (52). These data demonstrate that postnatal activation of LCS remodeling can dramatically alter  
138 the LCS even in robustly-mineralized cortical bone. Recent transcriptomic data from adult mouse long  
139 bones further support this premise. The osteocyte transcriptome is enriched for genes implicated in  
140 mineral and matrix resorption (e.g., cathepsin K, tartrate resistant acid phosphatase, vacuolar ATPase

141 family), demonstrating that osteocytes retain the capacity to modify their surrounding canalicular  
142 architecture in a manner consistent with development (53).

143 An intriguing potential role of LCS remodeling, which would further integrate LCS remodeling  
144 and mechanoadaptation, is a mechanism to achieve strain amplification to engage remodeling (54–56).  
145 Digital image correlation studies show that strains are amplified near osteocytes, but the reasons for this  
146 result are not clear (57). In particular, it is plausible that osteocytes could engage LCS remodeling to  
147 amplify or dampen mechanical signals by altering the shape of lacunae and canaliculi or the compliance  
148 of the surrounding bone (56). However, whether the osteocyte can actively modulate its own  
149 mechanosensitivity through LCS remodeling is not determined.

150 Another question is whether LCS remodeling contributes to bone fracture resistance (13).  
151 Genetic mouse models that interfere with TGF $\beta$  or YAP/TAZ signaling decrease LCS remodeling and  
152 produce a phenotype similar to skeletal aging, including decreased fracture toughness (49,51,58). These  
153 results, together with truncated LCS geometry in aging (37,38,59), suggest that LCS remodeling may  
154 have a role in maintaining bone fracture resistance in youth and that this process is decreased in aging.  
155 However, whether LCS remodeling serves to toughen bone is not determined. The LCS surface area is  
156 enormous, with a surface area on par with a tennis court (215 m<sup>2</sup>) and an end-to-end length of 175 km  
157 (13). LCS remodeling may thus result in the frequent turnover of an immense quantity of bone and  
158 decrease overall bone tissue maturity (i.e., increases the quantity of bone tissue with lower  
159 mineralization, less crosslinking, and less microdamage), which could serve to increase bone fracture  
160 resistance (11). Additionally, the loss of viable osteocytes and consequent micropetrosis could also  
161 deleteriously impact bone toughness (60–63). Establishing the significance of LCS remodeling to bone  
162 fracture resistance necessitates first determining the specific impacts of LCS remodeling on bone  
163 mineral, matrix, and multiscale bone quality.

164 While many open questions remain (**Box 1**), we are excited for the developments that coming  
165 years will bring toward resolving the purposes of LCS remodeling. We anticipate that ascertaining how,  
166 when, and why LCS remodeling may be controlled for therapeutic benefit could have a significant impact  
167 on our understanding and treatment of bone diseases.

168

## 169 **2. What are the impacts of LCS remodeling on bone mineral?**

170 Osteocytes very clearly can demineralize bone. Qiu and Bonewald’s seminal work demonstrated  
171 that osteocytes expand their surrounding lacunae in response to lactation in C57Bl/6 mice fed low  
172 calcium diet and that weaning reverses the lacunar expansion (4). Demineralization also occurs around  
173 canaliculi (64–66), although the spatial extent to which acids and matrix degrading proteins produced by  
174 osteocytes can affect more distant locations along canaliculi is not known.

175 Osteocytes also deposit bone mineral. Recovery of LCS architecture after lifting resorption  
176 pressure (e.g., weaning) demonstrates that osteocytes do produce new bone (4,6,49). Perilacunar bone  
177 formation has been visualized in rodents and humans by the systemic injection of calcium-binding  
178 fluorochromes (4,12,40,49,51,67,68). While classically applied to quantify osteoblastic mineral  
179 deposition on bone surfaces, high resolution imaging reveals extensive fluorochrome labeling of both  
180 osteocyte lacunae and canaliculi (**Figure 1A**). Notably, the perilacunar fluorochrome signal is typically  
181 not visible at light intensity thresholds that are optimal for analysis of osteoblastic surface deposition.  
182 Perilacunar labeling is abundant, including in cases outside of extreme challenges to mineral  
183 homeostasis (12,49,51). In young adult C57Bl/6 female or male mice, the majority (60-80%) of cortical  
184 femur and tibia lacunae show a fluorochrome label when administered calcein or alizarin 2 days before  
185 euthanasia (12,51). Lacunae can also show sequential double labels (**Figure 1B,C**). Because fluorochrome

186 labels are present for newly formed bone or newly exposed bone surfaces (i.e., following resorption),  
187 interpreting double labels for osteocyte lacunae requires scrutiny. The presence of sequential double  
188 labels, such as after weaning in lactation studies, is strongly suggestive of perilacunar mineral deposition  
189 (4). Interestingly, osteocyte-specific deletion of the mechanotransducers, YAP and TAZ, or global  
190 MMP13 knockout, decrease the percentage of labeled lacunae (49,51). These data indicate that LCS  
191 mineralization is regulated by osteocyte signaling.

192 Osteocytes likely express mineralization promoters and inhibitors, but the details of their  
193 specific control over local mineralization are largely unknown. Most bone mass is spatially associated  
194 with regions of high canalicular density (66), which suggests osteocyte mineralization promotion.  
195 Osteocytes also participate in mineralizing osteoblast-produced osteoid (64). Meanwhile, there is a  
196 'halo' zone of lower mineralization immediately adjacent individual canaliculi that suggests local mineral  
197 inhibition (64). Additionally, lacunar infilling with mineral (i.e., micropetrosis) is a characteristic of aged  
198 human bone with fewer viable osteocytes that likely produce fewer mineral inhibitors (60–63). These  
199 data suggest that osteocyte-produced mineralization inhibitors and promoters influence the location  
200 and quantity of mineralization. The specific identities of mineralization inhibitors for early and mature  
201 osteocytes are not understood. Also uncertain is whether osteocyte-produced extracellular vesicles  
202 (EVs) participate in regulating local bone mineralization. EVs travel through the LCS and can affect  
203 structures as far afield as the brain (8,9,69). Matrix vesicles (MVs) secreted by osteoblasts are directly  
204 shown to promote mineral nucleation from within the MV and can also bind to collagen (70). Whether  
205 osteocytes secrete matrix vesicles to nucleate mineral along the LCS is undetermined.

206 The maturation dynamics of bone formed by the osteocyte are also uncertain. In osteoid formed  
207 by osteoblasts, primary mineralization takes 7-10 days and accounts for 70% of bone mineral (71,72).  
208 Osteoblast-formed bone also matures with regards to crystal perfection and carbonate substitution  
209 (73,74), but whether this is true of osteocyte-deposited bone has not been reported. Since bone  
210 mineralization and demineralization appear to be frequently activated by osteocytes, it is possible that  
211 matrix close to a healthy osteocyte infrequently achieves a highly mature state. Supporting this idea,  
212 synchrotron phase contrast studies from human and sheep bone show mass gradation around lacunae  
213 and canaliculi. The lowest mass (i.e., mineral) content is directly adjacent to the walls of lacunae and  
214 canaliculi and a peak is reached 200-400 nm away (66). Additional work demonstrates that mineral  
215 thickness is higher close to lacunar and canalicular walls within areas of dense osteocyte networks (75).  
216 These findings prompt comparisons with the 'lacunar brush border' of incompletely dense, needle-like  
217 minerals at the fringe of osteocyte lacunae witnessed nearly 50 years ago in electron micrographs by  
218 Bonucci and Gherardi (23). Together, these studies suggest that bone tissue maturation local to the LCS  
219 is likely, but the dynamics of this process and the connections to osteocyte resorption and deposition  
220 activity are much less certain.

221 While rough estimates of the relative amount of calcium mobilized by LCS remodeling relative to  
222 osteoclastic resorption exist, precise measurements are needed to understand the role of the osteocyte  
223 in participating in systemic mineral homeostasis in reproduction, health, aging, and disease. The most  
224 fundamental questions include how osteocytes regulate peri-LCS mineralization, where and when bone  
225 mineralization and demineralization occur, and over which spatial and timescales LCS bone matures  
226 (**Box 1**).

227

### 228 **3. What are the impacts of LCS remodeling on organic bone matrix?**

229 Osteocytes have the ability to degrade organic matrix, as indicated by the lack of lacunar  
230 expansion for lactating MMP13-null mice (49). Demineralized bone is found around lacunae, as can be  
231 observed from histological studies. In a comparison of Wistar rats treated with either 4 weeks of

232 subcutaneous PTH or vehicle, the vehicle rats show a thin band of matrix surrounding cortical tibia  
233 osteocyte lacunae positive for both hematoxylin and toluidine blue. These bands appeared as prominent  
234 perilacunar belts in PTH-treated rats, which also showed lacunar expansion (21). However, it is unclear  
235 whether this tissue was residual matrix after mineral resorption or instead new osteoid produced by  
236 osteocytes.

237 Whether osteocytes produce osteoid is currently debated. Several lines of evidence support that  
238 osteocytes likely have this ability. Multiple studies from mouse long bones show abundant transcripts  
239 for ECM production, including type 1 collagen (*Col1a1*, *Col1a2*), osteocalcin (*Bglap*), and osteonectin  
240 (*Sparc*) (53,76). In some cases, the expression of these ECM genes (e.g., *Col1a1*, *Bglap*) can be even  
241 higher for osteocytes than for osteoblasts, such as shown in a recent laser capture microscopy analysis  
242 of rat vertebrae (77). Additional evidence for the osteocyte production of osteoid comes from  
243 fluorochrome labeling and histological studies. Serial double labeling has been reported for osteocyte  
244 lacunae from post-lactation mice, which implies the formation of osteoid (**Figure 1 B-C**)(4). Serial  
245 osteopontin bands around lacunae were seen for Wistar rats, also suggesting serial matrix formation  
246 events (20). Radiolabeling studies showed [<sup>3</sup>H] proline-labeled collagen around cortical lacunae from  
247 egg-laying hens during a period of calcium repletion (32,78,79). The irregular edges around these  
248 lacunae suggested, but did not confirm, prior bone removal. In humans, osteocyte-centered histological  
249 measurements were compared for Villanueva osteochrome-stained transiliac bone biopsies from  
250 hemodialysis (CKD) and osteoarthritic (OA) groups (40). Both CKD and OA groups showed osteoid-  
251 positive lacunae, but the number density of osteoid-positive lacunae was much greater for CKD patients  
252 with high PTH than either CKD-low PTH or OA. Dallas and colleagues recently developed a mouse model  
253 in which the topaz variant of green fluorescent protein (*GFP<sub>tpz</sub>*) was inserted into the mouse pro  $\alpha 2(I)$   
254 collagen N-terminus with expression driven by the 3.6-kb type I collagen promoter (35,80). These mice  
255 exhibit bright bands of GFP signal around osteocytes (80). Lactating mice, fed a low-calcium diet to  
256 maximize skeletal calcium mobilization, had significantly reduced collagen-GFP signal (35). On recovery,  
257 serial bands of GFP-collagen appeared in the perilacunar matrix (S. Dallas, personal communication).  
258 While these several studies provide evidence for osteocyte ECM production, there is still considerable  
259 uncertainty about what osteocyte produces and when. Very few osteocyte investigations considered  
260 organic matrix, perhaps because this information is not readily available using methods commonly  
261 utilized to study LCS geometry (e.g., high resolution CT).

262 If osteocytes do produce osteoid, several questions become pertinent. There may be important  
263 compositional and functional differences between osteocyte- and osteoblast-produced osteoid. It would  
264 be valuable to discern which osteocyte-produced proteins are incorporated into mineralizing osteoid  
265 produced by osteoblasts versus into new matrix around osteocytes. The maturation of the collagen  
266 matrix is also of interest. Does LCS bone resorption and deposition decrease the maturity of the collagen  
267 matrix, and would insufficient turnover decrease the quality of this matrix? Whether osteocytes directly  
268 influence or regulate the post-translational modifications of proteins in bone extracellular matrix is  
269 unknown. It is possible, but not yet shown, that the osteocyte could participate in the regulation of  
270 enzymatic and nonenzymatic collagen crosslinking and therefore impact collagen maturity. Answering  
271 these questions will require focused investigations at measurement scales relevant to osteocyte bone  
272 resorption and reformation (i.e., hundreds of nanometers) (**Box 1**).

273

#### 274 **4. What are the effects of LCS remodeling on bone quality?**

275 LCS remodeling alters perilacunar bone quality and impacts tissue-level material behavior (11).  
276 Most investigations of LCS remodeling on bone quality have employed microscale tools (e.g., Raman  
277 spectroscopy, backscattered SEM, nanoindentation) to assess the gradation of bone stiffness or

278 composition with distance from lacunae. In young adult mice, bone properties are usually similar  
279 between bone 1-5 micrometers from lacunae and farther away (e.g., 7-15  $\mu\text{m}$ )(10,34,81). In  
280 circumstances that challenge mineral homeostasis, such as lactation, kidney disease, glucocorticoid  
281 treatment, or PTH administration or endogenous expression from exercise, bone close to osteocyte  
282 lacunae is less mineralized or less stiff than at farther distances (4,34,81,82). However, outside of these  
283 contexts, resolving the impact of LCS remodeling on the surrounding tissue requires zooming in by at  
284 least an order of magnitude (11). Synchrotron phase contrast and transmission electron microscopy  
285 studies show that bone composition near the LCS is graded at the scale of hundreds of nanometers (66).  
286 In these studies, the lowest mineralization was seen immediately adjacent to lacunar and canalicular  
287 walls, which increased to a peak value 200-400 nm away. These gradations were reduced for lacunae  
288 from necrotic, glucocorticoid-treated bone compared with healthy mandibles, suggesting that osteocyte  
289 health may influence LCS bone material properties (66).

290 We recently found a more direct connection between osteocyte LCS activity and local bone  
291 quality (12). We mapped bone modulus at nanometer-scale resolution using atomic force microscopy  
292 (AFM) in defined regions around fluorochrome labeled and nonlabelled lacunae in the cortical femur for  
293 5 mo and 22 mo C57Bl/6 female mice. A similar profile of modulus versus distance from LCS walls was  
294 found from these AFM maps as for mineral gradation seen in prior synchrotron studies (12,66). Modulus  
295 initially increased from a minimum value along the lacunar wall to a maximum value 200-400 nm away.  
296 Labeled and non-labelled lacunae had a similar shape of gradation (i.e., similar initial rise and also  
297 location of peak value), but for labeled lacunae at both ages the gradation was shifted downwards  
298 towards lower moduli. Of note, perilacunar modulus gradation depends on hydration. For dehydrated  
299 bone, perilacunar modulus gradation closely corresponds to those seen in synchrotron microscopy and  
300 likely indicates gradation in mineralization. For hydrated bone, there is also a sharp modulus increase  
301 over the first  $\sim$ 400 nm from the lacunar wall, followed by a gradual increase to a peak modulus at  
302 approximately 1 micrometer away. Notably, this characteristic length corresponds with the distance  
303 from which 60% of bone mineral is located from the nearest lacunar or canalicular surface (75). An  
304 interesting question is if mineral and modulus gradations local to osteocytes influence strain  
305 experienced by the osteocyte. The more compliant tissue close to the LCS would be expected to amplify  
306 strain (56). Control over material gradation near the LCS may constitute a mechanism by which  
307 osteocytes regulate strain amplification. If this mechanism exists, and if it is impaired with decreased  
308 osteocyte viability in aging, are unresolved questions.

309 Several persistent questions need to be resolved about the impacts of LCS remodeling on bone  
310 quality. It is important to identify which tissue-scale toughening mechanisms, if any, are specifically  
311 impacted by LCS remodeling. Measurement of how much mineral and matrix are each resorbed and  
312 replaced by the osteocyte, and how these activities vary with skeletal location, sex, and across the  
313 lifespan, are needed to assess whether LCS remodeling 'adds up' as a mechanism by which the osteocyte  
314 can promote bone fracture resistance (**Box 1**).

315

## 316 **6. Discussion**

317 Fundamental questions about the role and impacts of LCS remodeling on bone currently limit  
318 our ability to interact with this system for therapeutic benefit. These questions are also implicit in the  
319 lack of consensus about what to call this physiological process. Since Belanger coined the term  
320 'osteocytic osteolysis', the names used to describe this phenomenon have evolved and now include  
321 perilacunar remodeling, perilacunar-canalicular remodeling, lacunar-canalicular network remodeling,  
322 and lacunar-canalicular system remodeling. Notably, whether 'remodeling' is an appropriate description  
323 of the bone resorption and deposition activities of the osteocyte is unresolved. Remodeling, as

324 understood from the perspective of conventional bone histomorphometry, implies the coupled removal  
325 and replacement of bone tissue by the basic multicellular unit (29,30,83). While we now agree that the  
326 osteocyte performs bone resorption and replacement, whether these activities are coordinated has not  
327 been demonstrated and the nature of the re-deposited matrix is under debate. 'Modeling' may be more  
328 appropriate, which refers to the uncoordinated removal or deposition of bone. This process serves to  
329 adapt and optimize the shape of bone in response to changing loading demands (or disuse) (30). It could  
330 be that LCS remodeling should be thought of as serial modeling activities. Another candidate is  
331 'turnover', indicating that bone is removed and replaced, but without the coordination of remodeling  
332 nor the specific functionality of modeling. This wording is conventionally used in the context of mineral  
333 exchange (30). At the moment, 'LCS turnover' is probably the most conservative description for these  
334 osteocyte bone resorption and formation process, but the name can and should evolve with our  
335 understanding of why, when, and how the osteocyte interacts with its surrounding mineral and matrix.

336 Most of the persistent knowledge gaps about the osteocyte can be classified in two categories  
337 with unique technical challenges. The first category is centered on how the osteocyte affects its local  
338 environment over space and time. While monitoring the size and shape of lacunae and canaliculi is  
339 useful for revealing large phenotypes (i.e., LCS expansion in lactation or truncation in aging) and is  
340 tractable via many common tools, this approach does not answer questions about how and when bone  
341 is resorbed or formed by osteocytes. A smaller lacuna could result from bone formation or, alternatively,  
342 but the cessation of resorption. Bone histomorphometry techniques are in many cases well-suited to  
343 improve our understanding about the temporal and spatial dynamics of LCS bone resorption and  
344 deposition. Also unresolved is how LCS remodeling impacts surrounding bone maturity and material  
345 properties. We now understand the need to 'zoom in' to witness the impacts of the osteocyte on its  
346 surrounding bone. Highly resolved tools, such as AFM, are useful for making progress in this space. We  
347 note that AFM on bone is technically challenging, requiring very smooth surfaces and stiff cantilevers  
348 (11,12). Performing AFM on hydrated bone introduces additional testing considerations (12).

349 A second category of questions is about the connection between osteocyte health and behavior  
350 on LCS remodeling. Because decalcification is necessary to assess osteocyte viability and protein  
351 production and is usually incompatible with studying the material properties of bone tissue, there are  
352 many longstanding questions about how osteocyte health and behavior influence LCS remodeling and,  
353 as a consequence, tissue properties. Our best tools are currently focused on affecting ensembles of  
354 osteocytes through genetic or pharmacological interventions and then assessing many of these cells. In  
355 complex processes such as aging, where osteocytes may be healthy, apoptotic, or senescent, the specific  
356 states of health of individual cells may differently affect LCS remodeling. Surmounting this major  
357 technical challenge is needed to link structure and function and accelerate our understanding of why  
358 and how osteocytes modify, or fail to modify, their surroundings.

359 While the prominence of studying LCS remodeling as a scientific pursuit has waxed and waned  
360 over the decades, now is a particularly exciting time to be studying this phenomenon. Many open  
361 questions regarding the purpose, the nature, the dynamics, and the impacts of LCS remodeling on bone  
362 tissue remain. We posit that answering these questions will be essential to ascertain whether, how,  
363 when, and why intervention in LCS remodeling may be exploited for therapeutic benefit. While our  
364 understanding to date of this scientifically fascinating and physiologically important phenomenon  
365 remains nascent, with the critical mass of researchers interested in this topic, new tools and models  
366 available, including cross-species comparative biology, we are enthusiastic about the insights the coming  
367 years will bring and their future impact on skeletal medicine.

368

369 **ACKNOWLEDGMENTS**

370 The authors thank Ghazal Vahidi for generating confocal laser scanning microscopy images of osteocyte  
371 lacunar-canalicular networks. Funding for this work was provided through NSF CMMI2120239 (CMH);  
372 NIH RO3AG068680 (CMH); NSF CMMI1548571 (JDB), NIH R21AR071559 (JDB). Any opinions, findings,  
373 and conclusions or recommendations expressed in this material are those of the author(s) and do not
