Algae

Algal biofuels represent a renewable, potentially viable, solution to mitigate transportation fuel demands. A novel diatom strain, RGd-1, isolated from Yellowstone National Park, produces high concentrations of lipids that can be converted to biodiesel. To increase the cell concentration and determine optimal conditions for growth, RGd-1 was grown without added Si, in the presence of four Si concentrations within the soluble range (0.5–2 mM), and one above the soluble range (2.5 mM). Medium Si concentrations and intracellular triacylglycerol (TAG) content were monitored daily by inductively coupled plasma mass spectrometry and Nile Red fluorescence, respectively (end-point TAG values were measured using gas chromatography). Si depletion with or without combined nitrate (NO_3^-) limitation was shown to induce TAG accumulation. Additionally, the effects of sodium bicarbonate (NaHCO_3) supplementation were examined on cultures grown using two NO_3^- concentrations (2.94 and 1 mM NO_3^-), which also resulted in increased TAG accumulation. It was determined that utilizing a combination of two independent physiological stresses and HCO_3^- supplementation resulted in the highest total and per cell TAG accumulation.

Introduction

Algal biofuels represent a potential alternative to petroleum-based transportation fuels. Capturing up to 2 g of atmospheric CO_2 per gram of biomass, algae utilize a problematic greenhouse gas while producing biodiesel precursors [1,2]. The 2007 Energy Independence and Security Act and Renewable Fuel Standard (RFS) sought to increase the contribution of renewable sources for energy production as well as decrease in greenhouse gas emissions. The RFS calls for production of 36 billion gal of renewable fuels by 2022 [3,4]. To meet this requirement, fundamental research is still required to improve the algal biofuel viability. Specifically, research into improved strain selection and culturing strategies to enhance algal biodiesel potential (BP)¹ have been identified as having the highest potential impact [5]. Paramount to algal biofuel feasibility is strain selection [6–8]. Some algal strains naturally contain high lipid concentrations in the form of triacylglycerol (TAG) [9,10]. Promising strains for use in biofuel production should have fast growth rates and high TAG content [3,8]. In most cases, substantial TAG accumulation does not occur while cells are rapidly growing, rather, TAG accumulates when cells are stressed by factors such as nutrient depletion, pH, temperature, light intensity or photoperiodicity [11–13]. When faced with nutrient limitations such as Si,² diatoms appear to direct carbon storage towards TAG, which can be converted for use in biodiesel production [14]. In addition to Si depletion, nitrogen stress and chemical addition are alternative methods to induce TAG accumulation in diatoms. For instance, Gardner et al. [10,15] combined nitrate depletion with sodium bicarbonate (NaHCO_3) addition, to accelerate TAG accumulation in green algae (*Scenedesmus* sp. & *Chlamydomonas reinhardtii*) and the diatom, *Phaeodactylum tricornutum* during the late exponential growth phase just prior to NO_3^- depletion. The results demonstrated that HCO_3^- addition can induce TAG accumulation across diverse taxa including freshwater and marine strains of green algae and diatoms. Another

¹ Triacylglycerol (TAG), monoacylglycerol (MAG), diacylglycerol (DAG), fatty acid methyl esters (FAME), dissolved inorganic carbon (DIC), Yellowstone National Park (YNP), Field Emission-Scanning Electron Microscopy (FE-SEM), inductively coupled plasma-mass spectrometry (ICP-MS), ion chromatography (IC), photosynthetically active radiation (PAR), dry cell weight (DCW), ash free dry weight (AFDW), biofuel potential (BP), gas chromatography–mass spectrometry (GC-MS), gas chromatography–flame ionization detection (GC-FID), relative fluorescence units (rfu), internally transcribed spacer (ITS).

² The dissolved forms of silica are monomeric and dimeric silicic acid ($\text{Si}(\text{OH})_4$), which diatoms incorporate into their cell walls in the solid form of silica (SiO_2). In an attempt to simplify this matter, the dissolved and solid forms of silicon will herein be referred to as Si and silica, respectively.

study by White et al. [16] observed increased total lipid per cell when two marine species, *Tetraselmis suecica* and *Nannochloropsis salina*, were cultured in two different concentrations of HCO_3^- from the onset of each experiment. While their data indicate increased lipid accumulation, their results did not display the dramatic rate of increase observed by Gardner et al. [10] when HCO_3^- was added just prior to NO_3^- depletion.

Here we focus on a diatom strain, designated RGd-1, isolated from an alkaline stream in Yellowstone National Park, USA. Diatom cell numbers and TAG accumulation were increased through the control of Si and NO_3^- concentrations as well as the addition of HCO_3^- . To our knowledge this is the first investigation using two combined physiological stresses and HCO_3^- addition to increase lipid accumulation in diatoms. The goals of this study were to (1) determine the optimal Si concentration for RGd-1 growth and lipid accumulation and (2) increase lipid content per cell by combining physiological stresses, including Si/ NO_3^- limitation and the addition of HCO_3^- for the diatom isolate RGd-1.

2. Material and methods

2.1. Diatom isolation and molecular characterization

RGd-1 (Fig. 1) was isolated from a sample collected from Witch Creek (pH 9.3) in the Heart Lake area of Yellowstone National Park (USA) containing both stream water and sediment. Environmental samples were streaked for isolation and individual colonies were selected and inoculated into various growth media types. This procedure was performed three times to ensure strain isolation, after which the cultures were treated with ampicillin to inhibit bacterial growth. Following this procedure, there was no evidence of bacterial growth upon inoculation of Bold's Basal Medium supplemented with 0.05% glucose and 0.05% yeast extract and incubated in the dark [17,18]. Additionally, RGd-1 was determined to be unialgal by clone library analysis using 25 clones each for both 18S rDNA and internally transcribed spacer (ITS) region as well as microscopic observation (light, epifluorescent, field emission-scanning electron microscopy (FE-SEM) and confocal laser scanning microscopy).

Based on frustule morphology observed using FE-SEM, the initial identity was thought to be a Navicula-like diatom [19]. Based on cellular morphology, RGd-1 resembles a Navicula-like diatom [19]. While cellular morphology may be used as a preliminary guide for identification, molecular techniques are also required. Amplification of SSU rDNA (18S), revealed that RGd-1 had the closest sequence similarity (96%) to *Lemnicola hungarica* with 99% sequence coverage [20,21]. Full length ITS amplification was additionally performed to obtain greater

resolution for strain identification, the results of which revealed 94% sequence similarity with its closest match, *Sellaphora pupula*. However, only 21% of the RGd-1 ITS region aligned to its closest match. To further clarify RGd-1 identity, the ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) large subunit (rbcL) was amplified and found to share 93% sequence similarity with 100% sequence coverage to *L. hungarica*. Considering that RGd-1 SSU rDNA had closest sequence similarity no greater than 96%, it likely belongs to a genus/species that has not been described thus far and further characterization is required.

DNA was extracted from 2 mL diatom samples by adding 200 μL of extraction buffer (1 M NaCl, 70 mM Tris, 30 mM NaEDTA, pH 8.6). The contents were centrifuged at 14,500 $\times g$ for 1 min and the supernatant discarded. Fresh extraction buffer (500 μL), sterile glass beads (1 mm), 125 μL 2% (w/v) CTAB (Tris-Cl, pH 8.0, 1.4 M sodium chloride, Teknova) extraction solution and 200 μL chloroform were added, and cells were disrupted by using a bead beater (Fastprep) at setting 6.5 for 45 s. Extracts were centrifuged at 12,000 $\times g$ for 15 min to separate the organic and aqueous phases. The aqueous phase was removed and dispensed into a sterile 1.5 mL centrifuge tube. To the extracts, 40 μL of 3 M sodium acetate were added as well as 5 μL of RNase (Promega) and 480 μL isopropanol (Molecular Grade, Fisher). The extract was incubated at 20 $^\circ\text{C}$ overnight and centrifuged at 12,000 $\times g$ for 15 min at 4 $^\circ\text{C}$ to pellet DNA. The pellet was washed with 200 μL of 80% ethanol and centrifuged again. Once the pellet was air dried in a biosafety cabinet, it was resuspended in 100 μL of 10 mM Tris-HCl. Template DNA was amplified using the following 18S primers UNI7F (5' ACCTGGTTGATCCTGCCAG 3') and 1534R (5' TGATCCTTCYGCAGGTTAC 3') [22,23] as well as ITS 1 (5' TCCGTAGGTGAACCTGCGG 3') and ITS 4 (5' TCCTCCGCTTATTGATATGC 3') [23–27]. Additionally, rbcL primers were used to obtain greater specificity using forward (5' GATGATGARAAYATTAATC 3') and reverse (5' ATTTGDCACAGTGDATACCA 3') primers [28]. Per 50 μL PCR reaction, 2.5 μL of each primer was added (final concentration 1 μM), as well as 25 μL of GoTAQ® Green Master Mix, 5 μL sample and 15 μL DNase/RNase free water. Samples were amplified by PCR with the following parameters: initial denaturation of 2 min at 94 $^\circ\text{C}$, followed by 40 cycles of 30 s at 94 $^\circ\text{C}$, 1 min at 52 $^\circ\text{C}$, 1.15 min at 72 $^\circ\text{C}$, and final extension of 7 min at 72 $^\circ\text{C}$.

Amplicons were run on a 0.7% agarose gel to verify size. The remaining amplification product was cleaned using a QIAquick PCR Purification Kit (Qiagen) and cloned using the pGEM®-T Vector System II (Promega). Clones were grown in LB + ampicillin (100 $\mu\text{g}/\text{mL}$) after which plasmids were extracted using the QIAprep Spin Miniprep Kit (Qiagen). Samples were submitted to Functional Biosciences (Madison, WI) for DNA sequencing, aligned using Jalview (version 2.8) [29], and the identity was determined using Megablast searches (NCBI).

2.2. Growth conditions

RGd-1 was grown in modified Bold's Basal Medium titrated to pH 8.7 (before autoclaving) with added sodium metasilicate ($\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$) (Sigma-Aldrich), S3 vitamin solution and Vitamin B₁₂, according to the ASP II medium recipe [18]. Preliminary screening results showed that RGd-1 gave the highest cell numbers and lipid accumulation when grown unbuffered at an initial pH between pH 8 and 9. Cultures were grown under 14:10 light/dark (L/D) cycle, aerated with ambient air resulting in the presence of 8–9 mg C L⁻¹ dissolved inorganic carbon (DIC) in a temperature controlled water bath (27 $\pm$ 1 $^\circ\text{C}$). Diatom cultures were grown in triplicate 1.25 L photobioreactors illuminated with 400 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ using twelve T5 4 ft fluorescent lights. The light intensity was measured using a photosynthetically active radiation (PAR) meter (LI-COR). Samples were collected daily just prior to the end of each light cycle. To quantify growth, a minimum of 400 cells were counted from each sample using a hemacytometer (Reichert) [30]. Sample pH was measured using a standard benchtop pH meter (Accumet). Prior to analysis by inductively coupled

Fig. 1. Field emission-scanning electron microscopy (FE-SEM) image of RGd-1.

plasma-mass spectrometry (ICP-MS), or ion chromatography (IC) analysis, samples were filtered using 0.22 μm filters (Whatman).

To increase diatom cell numbers, Bold's Basal Medium was modified with the following Si concentrations: 0.0, 0.5, 1.0, 1.5, 2.0 and 2.5 mM Si; with the last concentration being just above the solubility limit [31,32]. To determine whether testing conditions were statistically different, results were analyzed using a two-tailed Student's *t*-test assuming two samples with equal variances ($p < 0.05$).

To further increase the lipid content per cell and induce NO_3^- limited conditions by the time cells reached stationary phase of growth, the NO_3^- concentration was decreased from 2.94 mM (standard Bold's Basal Medium) to 1 mM NO_3^- . This modification created a dual stress (Si and NO_3^-) on RGd-1 cultures. Sodium bicarbonate (25 mM) was added to parallel cultures containing 1 mM or 2.94 mM NO_3^- . Each of these experiments contained 2 mM Si. At the completion of each experiment, cultures were centrifuged at 5000 $\times g$ for 10 min. The pelleted biomass was lyophilized (Labconco Lyophilizer) and later used for TAG and fatty acid methyl ester (FAME) analyses (described in Sections 2.6 and 2.7).

2.3. Dry cell weight (DCW)

Dry cell weight (DCW) was determined by filtering samples using GF/F Glass Microfiber Filters (Whatman). Samples were weighed after drying at 60 $^\circ\text{C}$ for approximately 24 h and re-weighed at 48 h to ensure all water had evaporated. Ash free dry weight (AFDW) was determined by heating DCW samples to 500 $^\circ\text{C}$ for 4 h [33,34]. The difference between the DCW and remaining ash is the ash free dry weight, which was approximately 70% of the DCW. Samples were weighed immediately upon retrieval from the furnace to minimize air vapor condensation.

2.4. Nitrate and chlorophyll concentration

Nitrate concentrations were measured by ion chromatography using an AS22 Anion-Exchange Column (Dionex) with a 4.5 mM NaHCO_3 /1.4 mM Na_2CO_3 buffer as eluent at a 1.0 mL flow rate. Nitrate was detected using a CD20 conductivity detector, and results were analyzed on PeakNet 5.2 Chromatography Workstation software. Chlorophyll was measured by centrifuging 1 mL of culture at 5000 $\times g$ for 10 min, decanting and re-suspending in methanol. Samples were intermittently vortexed, sonicated and incubated at 4 $^\circ\text{C}$ for 1 h. Following incubation, samples were centrifuged again at 5000 $\times g$ (10 min) and read at 632, 652 and 665 nm (Genesys 10-S, Thermo Electron Corporation). Total chlorophyll concentrations were calculated by adding chlorophylls *a* and *c* according to the methods outlined by Ritchie [35].

2.5. Silicon quantification

Total elemental silicon was quantified by ICP-MS (Agilent Technologies 7500ce). Isotopes of ^{28}Si , ^{29}Si , and ^{30}Si were measured simultaneously for each sample run on ICP-MS. Total silicon was quantified using ^{28}Si as it was the most abundant isotope with the greatest signal to noise ratio.

2.6. TAG analysis

The TAG content was estimated daily by staining cultures with Nile Red (9-diethylamino-5H-benzo (α) phenoxa-zine-5-one) (Sigma-Aldrich) (0.25 mg/mL suspended in acetone), adding 4 $\mu\text{g}/\text{mL}$ sample [36] and quantified on a microplate reader (Bio-Tek) with 480/580 excitation/emission filters. An hour-long time course of Nile Red stained RGd-1 cultures revealed that a 4 min exposure to Nile Red resulted in maximum fluorescence. Cell cultures were diluted if cell concentrations were higher than 3×10^6 cells mL^{-1} to maintain Nile Red fluorescence linearity. Total Nile Red fluorescence was strongly correlated with TAG ($R^2 = 0.987$) which was in agreement with prior work [36–38]. Fold difference in Nile Red fluorescence (Fig. 8) was

calculated by dividing the 15 d Nile Red fluorescence values by the 2 mM Si control. Error bars were calculated using the Delta Approximation Method [39].

Typically, algal biodiesel is derived primarily from TAGs. TAGs were extracted from dry diatom biomass (20 mg) in 5 mL 1:1:1 chloroform/hexane/tetrahydrofuran solution (triple solvent) and quantified using gas chromatography-flame ionization detection (GC-FID; Agilent 6890 N) [15]. Samples were sonicated for a total of 2 min in the triple solvent, using four 30 second pulses in an ice bath. Extracts were centrifuged (1380 $\times g$) for approximately 2 min. 1 mL was removed and placed in a GC vial with 10 μL octacosane (10 mg mL^{-1} in triple solvent) as an internal standard. Samples were analyzed using GC-FID with 1 μL injections for quantification of free fatty acids, monoacylglycerols (MAGs), diacylglycerols (DAGs) and TAGs using calibration standards (Mono-, Di-, and Triglycerides Kit; Sigma) on a 15 m RTX biodiesel column (Restek) according to Gardner et al. [15].

2.7. FAME analysis

FAMES were extracted and quantified by direct in-situ transesterification [40] and GC-MS, respectively for quantification of the fatty acid profile, the degree of saturation, and total biodiesel potential from direct transesterification based on methods outlined by Bigelow et al. [41]. To perform transesterification, dry biomass (10 mg) was added to 1 mL toluene and 2 mL 0.5 M sodium methoxide (pure, titrated in methanol, Acros Organics). Samples were placed in 5 mL crimp cap serum vials and heated to 80 $^\circ\text{C}$ for 30 min with intermittent vortexing. After cooling, 2 mL of 14% BF_3 -methanol (Thermo-Scientific) were added and the vials were re-heated as described above. Once samples had cooled, 0.8 mL saturated NaCl and 1.0 mL hexane were added. Samples were centrifuged at 1380 $\times g$ for 2 min, after which, 1 mL was removed and placed in a GC vial with 10 μL octacosane as an internal standard. FAMES were quantified using gas chromatography-mass spectrometry (GC-MS; Agilent 6890 and 5973 Network MS). Dilutions (1:10) were performed if peak areas were greater than the linear range of the calibration standards (NLEA FAME mix; Restek, Bellefonte, PA), as occurred for C-16 and C-18 FAMES. All other fatty acids were quantified by integrating peak areas of undiluted samples.

3. Results

3.1. Si concentration

As part of a Yellowstone National Park algal isolate screening, diatom strain RGd-1 was found to naturally contain high concentrations of TAGs (evident by Nile Red fluorescence); however, the final cell concentrations were lower than desired. To improve upon these results, the growth medium (modified Bold's Basal Medium described above) was supplemented with six different Si concentrations: 0, 0.5, 1.0, 1.5, 2.0 and 2.5 mM Si. At the time of harvest, DCW (Table 1) was strongly correlated with the (starting) Si concentration ($R^2 = 0.965$). Growth medium without added Si supported approximately four cell doublings from the initial cell concentration at $6.4 \times 10^4 \pm 2.7 \times 10^4$ cells mL^{-1} , reaching a final cell concentration of $1.1 \times 10^6 \pm 2.7 \times 10^5$ cells mL^{-1} (mean $\pm$ standard deviation) as indicated in Fig. 2 A. Potential sources of Si to support diatom cell replication can be attributed to intracellular Si storage, potential carryover from the RGd-1 inoculum or leaching from the borosilicate glass (Fig. S.1). When grown in 2.5 mM Si, cell numbers reached $1.1 \times 10^7 \pm 1.3 \times 10^6$ cells mL^{-1} . Across each of the growth conditions, the cellular morphology and doubling time remained consistent at 29.4 ± 1.4 h (Table 1). Therefore, cultures containing higher Si concentrations exhibited an apparent increase in cell numbers (Fig. 2 B).

Initially, and contrary to expectations, the higher Si concentrations (2–2.5 mM) appeared to increase until it reached a maximum at seven days of growth (Fig. 2 B). For the 1.5–2.5 mM initial Si conditions,

Table 1

Mean and standard deviation of growth and lipid accumulation characteristics for RGd-1: exponential growth phase doubling time. Cell dry weight (DCW), ash free dry weight (AFDW), specific Nile Red fluorescence, % TAG (w/w), and % biodiesel potential (w/w). Final values were calculated using AFDW ($n = 3$). RGd-1 cultured with 1 mM NO_3^- and/or 25 mM HCO_3^- were each grown with 2 mM Si.

^a Cultured with 2.0 mM Si.

^b 25 mM HCO_3^- .

early concentration measurements appeared lower than expected. This may be due to silica polymer formation promoted by pH or autoclaving. Between pH 10.9–13.6, disilicate ions are the predominant silicate species, however, below pH 10.9, the disilicates polymerize into polysilicates or colloidal silica, that might have been removed during filtration prior to ICP-MS analysis [31]. Over time the polymers may have dissociated thus appearing as though the medium Si concentration increased.

Total chlorophyll (chlorophyll a + c) was measured daily to monitor diatom cell health (Fig. 3 A). Chlorophyll concentrations increased with (initial) Si concentrations up to 1.5 mM and then stabilized. As expected, there was an inverse relationship between the measured chlorophyll and nitrate concentrations with total NO_3^- uptake increasing with cell numbers. Whereas cultures grown without added Si utilized

less than 1% of the NO_3^- in the growth medium, cells grown in 2.5 mM Si utilized approximately 87% (Fig. 3 B). It should be noted that none of the cultures grown with 2.94 mM NO_3^- reached a NO_3^- limited lipid accumulation phase.

As shown in Fig. 4, cultures grown in higher Si concentrations reached higher maximum pH values and Nile Red fluorescence. When grown without added Si (0 mM Si), the medium pH remained constant throughout growth at approximately pH 7.8. Cultures grown with higher Si concentrations reached greater maximum pH values, which remained elevated for extended periods of time. This effect is likely due to increased photosynthetic activity resulting in higher utilization of H_2CO_3 or HCO_3^- from the growth medium, thus increasing the pH (Fig. 4 A). Once the pH exceeded approximately 8.5, Nile Red fluorescence

Fig. 2. Mean and standard deviation of (A) RGd-1 growth (cells mL $^{-1}$) for six silica concentrations (0–2.5 mM) and (B) Silica concentration in the growth medium over time ($n = 3$).

Fig. 3. Mean and standard deviation of (A) chlorophyll production and (B) NO_3^- removal from growth medium for RGd-1 grown in each silica concentration ($n = 3$).

Fig. 4. Mean and standard deviation of (A) medium pH and (B) Nile Red fluorescence for RGD-1 grown in each silica concentration ($n = 3$).

exhibited a nominal increase. However, once Si was depleted from the growth medium, total and specific Nile Red fluorescence increased drastically with the highest values associated with the 2 and 2.5 mM Si treatments. At the time of harvest, cultures grown with 2.5 mM Si reached $33,030 \pm 2440$ relative fluorescence units (rfu) which was more than ten times the final Nile Red fluorescence of 2522 ± 848 rfu for cultures grown without Si addition (Fig. 4 B). Of the Si concentrations tested, the specific Nile Red fluorescence per cell was the highest at 25 ± 6 and 29 ± 4 rfu for 2 and 2.5 mM Si treatments, respectively (Table 1).

RGd-1 grown in 2 mM and 2.5 mM Si yielded statistically the same cell concentrations, growth rates, AFDW, chlorophyll and Nile Red fluorescence. As verified using a two-tailed student t-test ($p = 0.963$, t critical = 2.120), there was no significant difference between 2.0 and 2.5 mM Si. Based on these results, 2 mM Si was chosen as the model Si concentration for further lipid accumulation studies under NO_3^- limitation and HCO_3^- addition.

3.2. Bicarbonate addition and nitrate limitation

The results in the studies described above indicate that increasing the Si concentration resulted in increased cell concentration and TAG accumulation. Building on the findings by Gardner et al., [9,10,42], we hypothesized that lipid accumulation could be further improved using two simultaneous nutrient limitations and the addition of HCO_3^- [10]. As shown in Fig. 3 B, RGD-1 never depleted the NO_3^- from standard Bold's Basal Medium. Therefore, to create coincident Si and NO_3^- limitation stresses, cultures were grown in 2 mM Si, and NO_3^- concentrations were decreased to 1 mM. Additionally, HCO_3^- was added to parallel cultures just prior to Si and/or NO_3^- depletion. For these experiments, cultures were grown in Bold's Basal medium at standard NO_3^- (2.94 mM) or limited NO_3^- concentration (1 mM), with or without HCO_3^- addition

(25 mM final concentration). Fig. 5 A shows the cell concentrations remained consistent across the four growth conditions tested with final cell concentrations ranging from $1.2 \times 10^7 \pm 3.7 \times 10^6$ cells mL^{-1} (2.94 mM NO_3^- without HCO_3^-) to $1.5 \times 10^7 \pm 1.2 \times 10^6$ cells mL^{-1} (2.94 mM NO_3^- with HCO_3^-) (Table 1, Fig. 5 A). Si was depleted by approximately 12 d for each of the four growth systems (Fig. 5 B). As expected, cultures grown with 1 mM NO_3^- depleted the medium of NO_3^- by approximately 10 d and cultures grown in standard NO_3^- concentration (2.94 mM NO_3^-) remained replete with NO_3^- (Fig. 5 C). After 12 d, cultures grown with 1 mM NO_3^- were found to contain less total chlorophyll than cultures grown with 2.94 mM NO_3^- (Fig. 5 D). For the 1 mM NO_3^- studies, once NO_3^- was depleted, chlorophyll began to decrease by 11 d, but was stable when grown in 2.94 mM NO_3^- . While chlorophyll degradation suggests diminished photosynthetic ability and consequent capacity to fix inorganic carbon, the results indicate that total and specific lipid accumulations were not adversely affected.

Cultures exposed to combined Si and NO_3^- limitation stresses and HCO_3^- addition exhibited higher Nile Red fluorescence (Fig. 5 E and Table 1). When grown under Si limitation alone, the total Nile Red fluorescence was $29,430 \pm 2440$ rfu. Combining Si and NO_3^- limitation resulted in a slight increase in Nile Red fluorescence to $36,683 \pm 9126$ rfu. When Si depletion was combined with HCO_3^- addition, there was a substantial increase in Nile Red fluorescence to $50,613 \pm 3134$ rfu. However, the most dramatic response was observed through the combination of the two physiological stresses and HCO_3^- addition resulting in a total Nile Red fluorescence of $57,122 \pm 1870$ rfu, or approximately twice the Nile Red fluorescence for cultures exposed to Si stress alone (Fig. 6).

Cultures exposed to additive stresses reached higher specific Nile Red fluorescence as well. When grown under one stress (Si depletion), the specific Nile Red fluorescence was 25 ± 6 (Table 1). With two stresses (e.g., Si and NO_3^- depletion or Si depletion with HCO_3^- addition), specific Nile Red fluorescence reached 29 ± 6 and 34 ± 2 , respectively (Table 1). However, when the two nutrient stresses were combined with HCO_3^- addition, the specific Nile Red fluorescence reached the highest values at 43 ± 6 rfu, which is evident in cultures that were imaged by transmitted light and epifluorescence microscopy (Fig. 7). Additionally, cultures with added HCO_3^- maintained a slightly higher pH when compared to controls (Fig. 5F). This trend was consistent at both 1.0 mM NO_3^- and 2.94 mM NO_3^- , indicating a possible pH stress, and dissolved inorganic carbon (DIC) increase, with greater potential for lipid accumulation. These results indicate that additive stresses have significant potential to increase both specific and total TAG production in diatom cultures.

3.3. Lipid quantification

With exception of cultures grown without added Si, all of the conditions tested resulted in very high TAG and BP content per weight of biomass. Compared to cultures without added Si which reached 11% (w/w) TAG and 40.2% (w/w) BP, all other conditions reached >32% (w/w) TAG and >70% (w/w) BP (AFDW) (Table 1). Fig. 8 shows the total TAG content (w/v) in each system as calculated by Eustance et al. [43]. It is evident that greater total TAG production was achieved when cultures were grown with higher Si concentrations especially when combined with limiting NO_3^- and supplemented with HCO_3^- . Fig. 9 summarizes the composition of the extracted lipids from RGD-1 produced from cultures grown with 2 mM Si. Each of the conditions tested resulted in similar FAME profiles as shown in Fig. 8. Approximately 95% of the FAMES were composed of C14:0, C16:0, C16:1, C18:0, C18:1–3 and C20:5. Specifically, C16:0 (35%) and C16:1 (30%) encompassed the highest percentage of FAMES. Cultures grown without added Si (0 mM Si) resulted in approximately one-half of the BP (40%) as compared to cultures grown where Si was present (BP = 70–80%) (Table 1).

Fig. 5. Mean and standard deviation of growth characteristics for RGd-1 grown in four conditions: standard medium nitrate concentrations (2.94 mM), 2.94 mM NO_3^- + 25 mM HCO_3^- , 1 mM NO_3^- , and 1 mM NO_3^- + 25 mM HCO_3^- . All treatments contained 2.0 mM Si initially. (A) Diatom cell growth (cells mL^{-1}), (B) Silicon removal from the growth medium, (C) NO_3^- removal from the growth medium (mM), (D) chlorophyll concentration (mg L^{-1}), (E) Nile Red fluorescence intensity, and (F) medium pH ($n = 3$).

4. Discussion

4.1. Effects of Si concentration

Previous studies have explored the role of Si limitation on lipid accumulation for various diatoms. However, these studies were performed on marine diatoms [44] (e.g., *Cylindrotheca* spp. [14,45], *Thalassiosira pseudonana*, and *P. tricornutum*) [46] grown in media containing lower

Si concentrations than employed here (up to an order of magnitude less). While the use of marine strains may be advantageous in large-scale outdoor raceway ponds to avoid using freshwater sources, the results presented here indicate that pursuing methods that increase the Si availability may lead to increased growth, which is important for improving algal biodiesel productivity.

Strains that thrive in extreme environments (e.g., high temperature, alkalinity or salinity) may have increased potential to be successful in outdoor raceway ponds [2,47,48]. Discovering novel strains with fast growth rates, high lipid contents and the ability to thrive in environments uninhabitable for competing (non-productive with respect to biofuel production) organisms is important for the industrial viability of algal biofuel production [2].

Based on doubling time, cell yield, DCW, TAG and biodiesel content, RGd-1 growth with 2 mM Si was chosen as the optimum Si concentration for growth, which is approximately an order of magnitude greater than seawater. Diatoms utilize Si as silicic acid $\text{Si}(\text{OH})_4$ either in the monomeric or dimeric form. Both forms are in equilibrium with polymers eventually leading to dissipation of silica polymers as the diatom cell numbers increase [31]. Concentrations exceeding Si solubility (>2 mM) may result in polymerization, rendering Si potentially less biologically available [32]. When grown in the presence of 4 and 8 mM Si, the doubling time increased to 33 and 37 h, respectively (data not shown). It is hypothesized that this occurred as a result of diatoms utilizing monomeric and dimeric $\text{Si}(\text{OH})_4$ faster than it was liberated from the silicate polymers.

It is evident that higher initial Si concentrations ultimately lead to greater TAG accumulation. When grown in higher Si concentrations

Fig. 6. Each bar represents the fold difference in Nile Red fluorescence intensities at 15 d for each treatment compared to the 2 mM Si control.

Fig. 7. Transmitted light (left) and epifluorescent microscopy images of RGd-1 stained with Nile Red (right).

(1.5–2.5 mM), cultures reached higher maximum medium pH, which can be attributed to hydroxyl ion production as a result of the utilization of HCO_3^- . Additionally, hydroxyl ions may be produced through the assimilation of NO_3^- [43,49] and Si(OH)_4 , respectively [31]. When grown in the presence of higher Si concentrations, the cell numbers increased, leading to greater CO_2 and NO_3^- utilization and concomitant pH increase. This effect was observed for all silica concentrations where higher silica concentrations resulted in higher culture pH values, which were maintained for longer periods of time. These cultures were less susceptible to pH decrease compared to the 0.5 mM and 1 mM Si conditions in which the pH decreased significantly around 10 and 11 d, compared to the 1.5–2.5 mM Si conditions. Once the cells reached stationary phase of growth following Si depletion, they exhibited decreased photosynthetic ability, which was evident by lower pH (due to the accumulation of H_2CO_3 in the growth medium). Cultures grown with higher Si concentrations reached higher pH values due to greater OH^- production associated with higher concentrations of NO_3^- and Si(OH)_4 assimilation. The high pH reached at higher Si concentrations likely exposed the diatom to a pH stress as well, which has been shown to increase lipid accumulation in some microalgae [9,10,13]. Importantly, increased Si concentrations resulted in a greater number of cells with potential to produce more total TAG. While it may be

economically impractical to add 2 mM $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ on a large scale, the results presented here demonstrate the potential to improve cell and lipid concentrations when supplemented with high Si concentrations. Other Si sources are being evaluated and characterized to advance the results of this study to more commercially relevant conditions.

4.2. Using additive stresses to increase TAG

RGd-1 is capable of growth at high pH, which is advantageous when HCO_3^- can be utilized as a carbon source. Because RGd-1 stores high concentrations of lipids, it is a promising candidate for biofuel production. Further, RGd-1 was exposed to Si and NO_3^- limitation along with HCO_3^- addition and potentially a pH stress, which improved the accumulation of lipids [9,10]. The addition of HCO_3^- served as both a buffer (pKa: 10.3) and a source of inorganic carbon for growth and/or TAG accumulation.

Nitrate limitation is known to decrease chlorophyll concentration, which has been shown to decrease photosynthetic rates in *Chlamydomonas reinhardtii* [50,51]. While N is a particularly important limiting nutrient in biofuel production for green algae [9,52–57], N limitation may increase lipid accumulation in diatoms as well [10,50,58,59]. Additionally, N depletion can limit protein synthesis required for desirable functions such as TAG accumulation [50]. However, the results of this study indicate that NO_3^- limitation did not result in decreased lipid accumulation, rather there was a slight increase compared to cultures grown in NO_3^- replete conditions. Previous studies by Olsen et al.

Fig. 8. Mean and standard deviation of MAG, DAG, and TAG of diatom AFDW (g L^{-1}) of RGd-1 of grown in each condition tested ($n = 3$). RGd-1 cultured with 1 mM NO_3^- and/or 25 mM HCO_3^- were each grown with 2 mM Si.

Fig. 9. FAME speciation as % total FAME in 2 mM Si cultures ($n = 3$).

[60] and Vulot et al. [61] revealed that for the diatom, *Thalassiosira weissflogii* and the coccolithophore, *Hymenomonas carterae*, NO_3^- and Si limitation resulted in halting the cell cycle at G1 and late G1 & G2, respectively. It is possible that the two combined nutrient limitations at different periods within the cell cycle may contribute to cellular stress, ultimately leading to enhanced lipid accumulation. These results indicate that the combination of Si and NO_3^- limitation has the potential to increase TAG accumulation in lipid producing diatoms.

In this study, Nile Red fluorescence increased once the pH had increased to above pH 9, prior to nutrient depletion as shown in Figs. 4A and 5F, which is similar to the observations reported in Gardner et al. [9,10,15]. Cultures exposed to coincident Si and NO_3^- limitations, as well as HCO_3^- , exhibited the highest Nile Red fluorescence intensities of all the conditions tested.

Previous studies have discussed the role of a carbon concentrating mechanism (CCM), involving carbonic anhydrase (CA) and bicarbonate transporter activity [62–65]. After switching from high (5%) to low CO_2 (atmospheric concentration) conditions, it is thought that CA and bicarbonate transporter activity increase, resulting in elevated inorganic carbon transport into the cell, and chloroplast in close proximity of RuBisCO and may potentially be stored as lipids [10]. Here RGd-1 cultures were not supplemented with CO_2 , such that by late exponential phase of growth, cultures were likely carbon limited, with increased carbonic anhydrase activity similar to the mechanism discussed by Gardner et al. [10]. Once the cultures were supplemented with HCO_3^- , carbonic anhydrases shuttled more inorganic carbon across both the cell and chloroplast membranes resulting in higher CO_2 concentrations near RuBisCO, leading to increased lipid accumulation. This idea is corroborated by an increase in α -carbonic anhydrase gene expression during stationary phase following NO_3^- and PO_4^{3-} depletion in *P. tricornutum* [59]. It is possible that the combination of cell cycle arrest at both G1 and G2 of the cell cycle, combined with enhanced CCM activity due to sodium bicarbonate addition leads to substantially higher lipid accumulation, as measured by Nile Red fluorescence.

4.3. Comparison of Nile Red and TAG

Lipid analysis by gas chromatography indicated that when Si was present, RGd-1 accumulated a minimum of 32% (w/w) TAG and 70% (w/w) biodiesel potential (FAME) normalized to AFDW. The BP (in g FAME per g of biomass) was found to be more than twice the percent TAG which is indicative of transesterification of other lipids (e.g. phospholipids) that contribute to biofuel potential as described by Wahlen et al. [66]. The results in Fig. 7 and Table 1 are promising (70–80% BP), even though some frustule breakage may have occurred during centrifugation as a part of the harvesting process. During the late stationary phase of growth, microscopic observations showed frustule breakage, with lipid vacuoles exiting the cells (data not shown). This phenomenon may potentially be beneficial for lipid extraction on a large scale, but might have resulted in an underestimation of the lipid productivity of RGd-1 cultures. A current obstacle in the algal biofuels industry lies in energy efficient and safe protocols to extract lipid from cells. Therefore, it is possible that choosing strains that rupture easily when full of lipid, may be advantageous for harvesting and lipid extraction. In fact, the advantage of easily breakable cell walls may increase the viability of diatoms for biofuel production, though overly fragile diatoms may lead to lipid loss and culture contamination by heterotrophs.

5. Conclusions

RGd-1 is a novel diatom with the ability to accumulate high concentrations of lipids, and has not been described previously. By increasing the Si concentration, we were able to effectively increase the cell concentration, but growth rates are still lower than desired. Once Si was depleted from the growth medium, lipid accumulation was promoted.

Further, the results of this study indicate that multiple combined stresses can enhance lipid accumulation, leading to higher lipid content and bio-fuel potential. Specifically, Si and NO_3^- depletion, combined with HCO_3^- addition, and potentially pH stress contributed to this increase. The ability of diatom cell walls to break easily when cells are full of lipid during the late stationary phase of growth may provide an advantage over green algae in regards to lipid extraction for use in biodiesel production. Further investigation is underway to determine optimal growth conditions for use in large-scale growth systems.
