A B S T R A C T

The \(0.93(\text{Bi}_{0.5}\text{Na}_{0.5})\text{TiO}_3-0.07\text{BaTiO}_3\) (BNB7T) piezoelectric single crystals and ceramics have been grown respectively by using the self-flux and solid-state-reaction methods. The real \((\varepsilon')\) and imaginary \((\varepsilon'')\) parts of the dielectric permittivity of BNB7T crystals and ceramics were investigated with and without an electric \((E)\) poling as functions of temperature and frequency. The BNB7T crystal shows a stronger dielectric maximum at \(T_m\sim240^\circ\text{C}\) than the ceramic at \(T_c\sim300^\circ\text{C}\). The dielectric permittivity of BNB7T ceramic shows an extra peak after poling at an electric field \(E=40\text{kV/cm}\) in the region of \(80-100^\circ\text{C}\) designated as the depolarization temperature \((T_d)\). A wide-range dielectric thermal hysteresis was observed in BNB7T crystal and ceramic, suggesting a first-order-like phase transition. The dielectric permittivity \(\varepsilon'\) obeys the Curie–Weiss equation, \(\varepsilon'=C/(T-T_0)\), above \(500^\circ\text{C}\), which is considered as the Burns temperature \((T_b)\), below which polar nanoregions begin to develop and attenuate dielectric responses.

1. Introduction

Lead-free ferroelectric\(\text{(FE)}/\text{piezoelectric polycrystalline ceramics have been developed in recent years because of environmental concern and global regulations. The \((\text{Bi}_{0.5}\text{Na}_{0.5})\text{TiO}_3\) (BNT)-based solid solutions substituted with various ions in the A or B sites of the perovskite unit cell have been extensively studied, such as BNT–
\text{BaTiO}_3 [1], BNT–(\text{Bi}_{0.5}\text{K}_{0.5})\text{TiO}_3 [2–4], BNT–\text{KNbO}_3 [5], BNT–\text{BiFeO}_3 [6], BNT–\text{SrTiO}_3 [7], and BNT–\text{BaTiO}_3–(\text{K}_{0.5}\text{Na}_{0.5})\text{NbO}_3 [8]. The BNT ceramic shows a large coercive field \((E_c=73\text{kV/cm})\) and remnant polarization \((P_r=38\text{\mu C/cm}^2)\) at room temperature [9]. The ferroelectric BNT relaxor has a high Curie temperature of \(T_c=320^\circ\text{C}\) [9–12].

Among lead-free piezoelectric materials, \((1-x)(\text{Bi}_{0.5}\text{Na}_{0.5})\text{TiO}_3-x\text{BaTiO}_3\) (abbreviated as BNB100\(x\)T) solid solutions reported firstly by Takenaka et al. [11] have been of particular interest because of the existence of a morphotropic phase boundary \((\text{MPB})\) near \(x=0.06–0.07\), whose piezoelectric properties appear similar to those of the \(\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3\) (PZT) piezoelectric ceramics.
(or nanoclusters) begin to develop below the Burns temperature at $T_b \approx 500$ °C in BNB7T crystal and ceramic, and cause the broad frequency-dependent dielectric responses.

2. Experiments

The BNB7T single crystals were grown using the high-temperature self-flux method. High-purity (> 99.9%) $\text{Bi}_2\text{O}_3$, $\text{Na}_2\text{CO}_3$, $\text{BaCO}_3$, and $\text{TiO}_2$ powders were used as starting materials, with $\text{Bi}_2\text{O}_3$ and $\text{Na}_2\text{CO}_3$ as self-flux materials. According to the compositional formula of (Bi$_{0.5}$Na$_{0.5}$)$_{0.93}$Ba$_{0.07}$TiO$_3$, stoichiometric amounts of powders were weighed and mixed in ethanol and milled with zirconia balls for about 24 h. The mixed powders were then calcined at 900 °C in an alumina crucible for 2 h, which yielded single-phase powders. The calcined BNB7T powders mixed with excess $\text{Bi}_2\text{O}_3$ and $\text{Na}_2\text{CO}_3$ flux were soaked at 1300 °C for 1 h in a platinum crucible and then cooled to 1050 °C in the ambient environment of the tube furnace. The BNB7T crystals grown with a cooling rate of 1 °C/h have larger sizes and show a light-yellow color with maximum dimensions of $8 \times 8 \times 5$ mm$^3$ as shown in Fig. 1(a). However, the BNB7T crystals grown with a faster cooling rate of 5 °C/h exhibit smaller sizes with a bluish color.

Polycrystalline BNB7T ceramics were synthesized using the solid-state-reaction method. Stoichiometric amounts of $\text{Bi}_2\text{O}_3$, $\text{Na}_2\text{CO}_3$, $\text{BaCO}_3$, and $\text{TiO}_2$ powders were used as starting materials and were mixed in ethanol with zirconia balls for about 24 h. The mixture was calcined at 900 °C for 2 h and a high-energy ball milling method using a Retsch PM100 planetary mill was employed to reduce particle size. The powder mixture was pressed into a 1.0 cm-diameter disk for sintering at 1150 °C for 1 h. The SEM photograph of Fig. 1(b) shows the morphology of sintered BNB7T ceramic with grain sizes of 1–3 μm.

Structures of unit cells were determined by using a conventional Rigaku Multiplex X-ray Diffractometer and high-resolution synchrotron XRD performed at the National Synchrotron Radiation Research Center (in Taiwan) with photon energy of 8.0 keV ($\lambda = 1.5498$ Å). The high-resolution synchrotron XRD peaks were fitted with Gaussian profiles. Two processes were used in the dielectric measurements with a Wayne–Kerr Analyzer PMA3260A. In the first process, the dielectric permittivity was taken upon heating and cooling without a prior dc $E$-field poling. In the second process, the sample was poled at room temperature with a dc $E$ field of 40 kV/cm, then dielectric permittivity was measured without a dc $E$ field. The coercive field ($E_c$) of BNB7T ceramic is about 30 kV/cm as shown in Fig. 2. The dielectric loss is defined as $\tan \delta = \varepsilon''/\varepsilon'$.

3. Results and discussion

Fig. 3(a) shows the conventional XRD of the as-grown BNB7T crystal at room temperature, indicating a (0 0 1) crystallographic orientation. The 2θ diffraction position and $d$ spacing obey the Bragg law $2d_\text{hkl} \sin \theta_\text{hkl} = n \lambda$, where $(h k l)$ is the crystallographic orientation. For a tetragonal unit cell, two $d$ spacings are expected from the $(2 0 0)$ or $(0 0 2)$ reflections according to the equations, $d_{200} = d_{020} = a_2/2$ and $d_{002} = c_1/2$. For a rhombohedral unit cell, one $d$ spacing is expected from the $(0 0 2)$ reflection, i.e., $d_{002} = a_0(1 - 3 \cos^2 \alpha + 2 \cos^2 3\alpha)^{1/2}/(4 \sin^2 \alpha)^{1/2}$.

The high-resolution $(0 0 2)$ synchrotron XRD of BNB7T crystal as shown in Fig. 3(b), reveals one rhombohedral $(R)$ and two tetragonal $(T)$ peaks, indicating coexisting phases of $R$ and $T$ structures. In addition to $R$ and $T$ reflections, an extra broad peak appears at lower 2θ, possibly indicating a coherent superposition of diffracted waves from nanostructures. Nanostructures are often expected in relaxor FE crystals to accommodate the lattice distortion [23,24]. From the fitting parameters, the lattice constants of the tetragonal unit cell are calculated to be $c_1 = 3.956$ Å and $a_2 = 3.893$ Å at room temperature. The XRD of sintered BNB7T ceramic is given in Fig. 3(c) and shows no splitting, suggesting a pseudocubic unit cell.
The dielectric permittivity and loss of (0 0 1)-cut BNB7T crystal (Fig. 4), show similar dielectric responses before and after poling at \( E = 40 \text{ kV/cm} \). This implies that the prior \( E \)-field poling did not affect the polarization ordering in the (0 0 1)-cut BNB7T crystal.

The room-temperature \( \varepsilon' \) of unpoled BNB7T crystal for \( f = 1 \text{ MHz} \) is about 1200, which is larger than \( \varepsilon'_\text{max} \approx 4400 \). The dielectric permittivity \( \varepsilon' \) below \( T_m \approx 240 \text{ C} \) exhibits an extensive frequency dispersion with a shoulder near 160 \text{ C}. The dielectric permittivity \( \varepsilon' \) above 500 \text{ C} obeys the Curie–Weiss equation, \( \varepsilon' = C/\left( T - T_0 \right) \), as indicated by the dashed lines with the constants of \( C = 2.4 \times 10^8 \text{ C} \) and \( T_0 = 340 \text{ C} \) for the unpoled crystal, and \( C = 2.6 \times 10^5 \text{ C} \) and \( T_0 = 340 \text{ C} \) for the poled crystal. The temperature of 500 \text{ C} is considered to be the Burns temperature \( \left( T_B \right) \), below which the polar nanoregions (or nanoclusters) begin to develop and attenuate dielectric responses under ac measuring \( E \) field. The dynamics of polar nanoregions is responsible for the broad dielectric dispersion [26].

The room-temperature dielectric losses of BNB7T crystal for \( f = 1 \text{ MHz} \) before and after poling are about 0.09, which is slightly larger than 0.05 in pure BNT crystal [25]. The dielectric loss exhibits a strong frequency dispersion and broad maximum in the region of 100–160 °C. This diffuse phenomenon suggests a relaxor FE feature and a progressive transition from the FE state to relaxor state at lower temperature region. A phase-shifted conductivity is evident at higher temperatures (\( > 500 \text{ C} \)), above which the dielectric loss is larger than 1 and rises exponentially with increasing temperature. The phase-shifted conductivity is mainly due to the thermally activated ionic conduction [27].

The dielectric permittivity and loss of BNB7T ceramic are given in Fig. 5 and exhibit very different dielectric responses before and after poling at \( E = 40 \text{ kV/cm} \). The dielectric permittivity of BNB7T ceramic shows an extra peak after poling at \( E = 40 \text{ kV/cm} \) in the region of 80–100 °C, which is designated as the depolarization temperature \( \left( T_d \right) \). These phenomena suggest that the prior \( E \)-field poling affects the low-temperature polarization ordering in BNB7T.
ceramic. The room-temperature $\epsilon'$ for $f=1$ MHz is about 1060 and 980 before and after poling, respectively. This slight decrease in $\epsilon'$ is likely due to the reduction of polarization disordering after poling along the measuring $E$-field direction. The dielectric maxima $\epsilon'_\text{max}$ of BNB7T ceramic appear at $T_m=300$ °C and are about 2800 and 2600 before and after poling. The dielectric permittivity $\epsilon'$ below 160 °C exhibits an extensive frequency dispersion. The dielectric permittivity $\epsilon'$ above 500 °C follows the Curie–Weiss equation as described by dashed lines with $C=2.3 \times 10^5$ °C$^{-1}$ and $T_0=320$ °C for the unpoled ceramic, and $C=2.4 \times 10^5$ °C$^{-1}$ and $T_0=320$ °C for the poled ceramic.

The room-temperature dielectric losses of BNB7T ceramic for $f=1$ MHz before and after poling have a similar value of 0.08. The dielectric loss of BNB7T ceramic after poling at $E=40$ kV/cm shows an extra peak in the region of 80–100 °C, suggesting a sequence of transitions from ordered to disordered states upon heating. The dielectric loss begins to increase exponentially for temperatures higher than 500 °C, implying that the high-temperature dielectric responses are associated with the phase-shifted conductivity [27].

BNB7T crystal and ceramic exhibit a wide-range dielectric thermal hysteresis in Fig. 6, suggesting a first-order like phase transition. The thermal hysteresis of BNB7T crystal begins below 500 °C and ends at $-120$ °C in Fig. 6(a). Based on Fig. 3(b) which shows an $R-T$ coexistence in our crystal at room temperature, and an $R-R+T-T-C$ transition sequence observed in a pure (0 0 1)-cut BNT crystal [25], we propose that the thermal hysteresis suggests a sequence of $R+T-T-C$ (cubic) phase transitions upon heating. In BNB7T ceramic, the thermal hysteresis occurs in the region of 130–250 °C. This broad thermal hysteresis likely corresponds to a gradual first-order structural transition from a coexisting $R+T$ to $T$ phases.

4. Conclusions

The dielectric permittivity and loss of BNB7T piezoelectric crystals and ceramics with and without a prior $E$-field poling, have been investigated as functions of temperature and measuring frequency. The (0 0 1)-cut BNB7T crystal shows stronger dielectric responses than the BNB7T ceramic. The dielectric permittivity and loss of poled BNB7T ceramic show a depolarization peak at 80–100 °C. However, the depolarization peak was not observed in the poled BNB7T crystal, indicating that the external $E$ field did not largely change the ordered state noticeably in the poled crystal. A wide-range dielectric thermal hysteresis was observed in BNB7T crystal and ceramic, suggesting a first-order-like phase transition. The dielectric permittivity $\epsilon'$ obeys the Curie–Weiss equation above 500 °C, which is considered as the Burns temperature ($T_B$), below which polar nanoregions (or nanoclusters) begin to develop.
