Abstract:
Twenty-six collections of twenty Aqropyron species were examined serologically using antigenic material from leaves. Antisera were produced in New Zealand white rabbits. Double-diffusion serological reactions in agar were used to interpret hybrids, putative hybrids and relations among plants of Aqropyron which contain the so-called B genome. Set notation is developed as a tool for describing and interpreting antigen-antibody precipitate lines in double-diffusion gel plates. Based on serological evidence four of the five putative hybrids studied are apparently seifs rather than hybrids. One putative hybrid could not be distinguished as either a self or a hybrid by serological means.

Data are presented which illustrate the complexity of the interaction between two genetic systems. Serologically four kinds of differences were found; 1) rabbit to rabbit differences illustrated by rabbits 009, 010 and 10-3 which did not respond the same to antigenic material from plant 10-3; 2) tissue to tissue differences illustrated by the comparison of the X-Re of antigenic material from culms and spikes of plant 10-3 with the R-Re of leaf antigenic material from plant 10-3; 3) plant to plant differences within a species illustrated by the A. intermedium intraspecific putative hybrid, the A. cristatiforme (16-1) X-Re with antiserum from rabbit 10-3 and the A. dasystachyum X-Re with antiserum from rabbit 147-s, and 4) species to species differences similar to those reported by Creel (1964).

A. spicatum (n=14) is considered a variable autotetraploid with genome formulae of SSSS to SSSxSx , where x is a varying amount of change in the different populations A. spicatum. A. arizonicum is considered to be a segmental allotetraploid and is given the genome formula of SSSBSB based upon serological data and supported by cytogenetic information.

Cryptic structural hybridity may not be distinguished in hybrid analysis or karyotype analysis. Morphological information has not shown the relationships of the Aqropyron. Serological information may be an important source of information in a biosystematic program but should not be considered as either superior or inferior to other systematic data.

ACKNOWLEDGMENT

Appreciation is expressed to Professor J. R. Schaeffer for advice and criticism during the course of this study; to Montana State University and the National Science Foundation for materials and space and to the United States Office of Education for an N. D. E. A. fellowship in Genetics.

The constructive criticism of Professor P. D. Skaar, Professor E. R. Hehn and Dr. S. R. Chapman is gratefully acknowledged as is the encouragement of many other members of the faculty and staff of Montana State University who are too numerous to mention.

This thesis is dedicated to my wife, Jan, without whose encouragement and understanding this study could not have been completed.

ABSTRACT

Twenty-six collections of twenty Agropyron species were examined serologically using antigenic material from leaves. Antisera were produced in New Zealand white rabbits. Double-diffusion serological reactions in agar were used to interpret hybrids, putative hybrids and relations among plants of Agropyron which contain the so-called B genome. Set notation is developed as a tool for describing and interpreting antigen-antibody precipitate lines in double-diffusion gel plates. Based on serological evidence four of the five putative hybrids studied are apparently selfs rather than hybrids. One putative hybrid could not be distinguished as either a self or a hybrid by serological means.

Data are presented which illustrate the complexity of the interaction between two genetic systems. Serologically four kinds of differences were found; 1) rabbit to rabbit differences illustrated by rabbits 009, 010 and 10-3 which did not respond the same to antigenic material from plant 10-3; 2) tissue to tissue differences illustrated by the comparison of the X-Re of antigenic material from culms and spikes of plant 10-3 with the R-Re of leaf antigenic material from plant 10-3; 3) plant to plant differences within a species illustrated by the A. intermedium intraspecific putative hybrid, the A. cristatiforme (16-1) X-Re with antiserum from rabbit 10-3 and the A. dasystachyum X-Re with antiserum from rabbit 147-s, and 4) species to species differences similar to those reported by Creel (1964).

A. spicatum (n=14) is considered a variable autotetraploid with genome formulae of SSSS to SSS_xS_x, where x is a varying amount of change in the different populations of A. spicatum. A. arizonicum is considered to be a segmental allotetraploid and is given the genome formula of SSS_BS_B based upon serological data and supported by cytogenetic information.

Cryptic structural hybridity may not be distinguished in hybrid analysis or karyotype analysis. Morphological information has not shown the relationships of the Agropyron. Serological information may be an important source of information in a biosystematic program but should not be considered as either superior or inferior to other systematic data.

INTRODUCTION AND LITERATURE REVIEW

In 1960 a research program concerned with the biosystematics of the genus Agropyron was initiated at Montana State University under the direction of Professor Jurgen R. Schaeffer. The present study was undertaken to investigate serology as a taxonomic technique and to detect genetic differences in Agropyron by means of serology.

The genus Agropyron contains approximately 150 species, of which 100 are native to Europe and Asia, 30 are native to North America and the remainder are found in South America, Australia, New Zealand and Africa.

Many species of Agropyron are of considerable economic importance. Many are excellent forage species and others are serious pests. Agropyron has been regarded as an artificial genus by numerous workers (Nevski 1934, Parodi - cited in Connor 1954, and Stebbins and Walters 1949). Stebbins and Walters were of the opinion that the established species names should be retained until adequate cytogenetic and morphological data permit the development of a more natural system. Beetle (1961) suggested that detailed field studies in the regions where the species are native are necessary before the true answers to the classification puzzles can be obtained. It is generally agreed that the status of the genus Agropyron is confused and that many of the species are not adequately defined within the taxa.

Parodi (cited by Connor, 1964) considered the genus Agropyron partly artificial in that separation of the South American Agropyron and Elymus could not be achieved by morphological characteristics. Gould (1947) placed the California species of Agropyron, Sitanion, Hystrix and Elymus

into one genus. Stebbins and Walters (1949) concluded that there was not enough evidence to determine the boundary of the genus.

Information of a biochemical nature has proven useful in taxonomic investigations (Alston and Turner 1963). Modern taxonomy takes into account all forms of information, especially those which are capable of detecting genetic differences. Serological techniques measuring genetic variation by antigen-antibody reactions may offer insight into problem areas of plant systematics.

The precipitin reaction was discovered by Kraus in 1897 (cited by Fairbrothers and Johnson 1964). Nuttall (1901) was the first to show the possible uses for this method in taxonomic investigations. Much serological work has been done with zoological classification. The earliest work at Montana State University was done by Martin and Cotner (1934) who investigated the serological properties of moth thorax antigens. They suggested that "...the application of immunological reactions in the determination of relationships between species of various organisms has brought to the hand of the systematist a new and exact method of determining phylogenetic relationships...supplementing...other studies in the classification of various biological groups".

The use of serology in plant investigations has been less advanced than in animal investigations. This may be explained by historical events in serobotany and the fact that serology began as a zoological method. Furthermore animal antigens, unlike plant antigens, are not accompanied by compounds such as alkaloids, which may be harmful to the experimental animal.

Kowarski (1901, cited in Hall 1959) was perhaps the first to use plant materials as antigens when he caused the production of antibodies in rabbits using heat resistant albuminose from wheat. These antibodies reacted strongly with wheat albumin extracts but weakly or not at all with extracts of rye, barley, oat and pea. He found what could be considered an antisystematic reaction when the reaction with the pea extract was stronger than that with the oat extract. Ballner and Burrow (1910) found rye serologically more closely related to wheat than to barley. This relationship is in agreement with Godley's view of the Triticeae (Hordeae) comparium (Godley 1951).

Rives (1923 a,b) and Green (1926) found the ability to graft successfully was accompanied by a distinct serological similarity in species of each of the taxa _Vitus_, _Citrus_, Rosaceae and Solanaceae.

Phytoserological activity reached a peak with the publication of Der Königsberger Serodiagnostische Stammbaum by Mez and Ziegenspeck (1926). This phylogenetic structure based on serology was severely criticized by Gilg and Schurhoff (1927) of Berlin. Moritz (1964) states "The...feud between the Königsberg school of Mez and the Berlin school of Gilg and Schurhoff...did much damage to the prestige and activity of the method among botanists". A thorough review of this conflict is given by Chester (1937). A few researchers, Johnson at Rutgers and Moritz at Institut für Pharmakognosie, Kiel, Germany, continued to experiment with the methods involved with plant serology.

Recent serological work deals mostly with small groups of closely related taxa at the family level or lower. Gell, Hawkes and Wright

(1960), working with the tuberous members of the genus Solanum, were able to show relationships corresponding to relationships based upon morphological and cytogenetic data. Lester (1964) expanded and continued this work. Johnson (1954) and Johnson and Fairbrothers (1965) found Liriodendron to be serologically distinct from the rest of the Magnoliaceae. Fairbrothers and Johnson (1964) and Fairbrothers (1966) studied the Cornaceae complex serologically and were of the opinion that the separation of the complex into Cornaceae with one genus and Nyssaceae with two genera was justified.

Brown and Lester (1965) found what they consider to be a probable error in the taxonomic placement of one species of green algae based on serological reactions.

Hall (1959) studied a stabilized polyploid hybrid between wheat and rye (Triticale) and found that all proteins identified in the wheat could be traced to the hybrid. Specific Triticale antigens were not found.

Sawyer (1967) was not able to separate the Montana species of Delphinium serologically. Ericson et al. (1967) found Populus tremuloides serologically distinct from other Populus studied.

Lester et al. (1965) found serological data conservative in that it delineated the genus but did not help to distinguish between the fourteen species of Baptista studied. It is their opinion that "there is no clear justification for regarding serological data as intrinsically either superior or inferior to other systematic criteria".

The discovery of the double-diffusion precipitin reaction in gels (Ouchterlony 1948) made a significant contribution to serotaxonomic

studies.

Ouchterlony (1964) discusses four types of serological reactions found in double gel-diffusion plates. The type I or identity reaction occurs when precipitate lines join in a smooth curve and are interpreted as being formed by identical or nearly identical antigens reacting with the same antibodies. The type II or nonidentity reaction occurs when lines cross another line and are interpreted as being caused by different reacting antigens. Type III or partial identity reactions cause the formation of a spur rather than a smooth curve and are taken to mean that nonidentical but similar antigens are reacting with the same or a closely related antibody. In the type IV or reaction-inhibition reactions, precipitate lines do not join in a meaningful pattern. The number of bands may not indicate the maximum number of antigen-antibody systems present since some of the bands may be obscured by others (Fairbrothers 1966, Kwapinski 1965). The antigenic material used to produce an antiserum is referred to as the "reference antigen" (R-Ag) and all other antigenic material which will react with this antiserum is considered a "crossreacting antigen" (X-Ag) (Williams 1964). The reaction observed when the antiserum is reacted with the reference antigen is the "reference reaction" (R-Re) while the reaction observed when the antiserum is reacted with any other antigenic material is considered a "cross reaction" (X-Re) (Fairbrothers 1966). Theoretically no cross reaction can produce more lines than the reference reaction. It may produce as many lines but probably will produce fewer (Moritz 1964).

The objectives of this study were: 1) to determine the serological behavior of known hybrids and to use the results to determine the success or failure of hybridization attempts and to make inferences about the relationships of the plants involved; and 2) to determine the serological relationship of the B genome in some of the tetraploid species of *Agropyron* such as *A. arizonicum* and *A. caninum* in relationship to the S genome found in the diploid *A. spicatum*.

MATERIALS AND METHODS

The concept of serology is based upon the fact that the introduction of a foreign substance of biological origin (antigen) into the circulatory system of an animal may give rise to the production of substances (antibodies) in the blood which are capable of affecting the introduced antigen in a number of ways. This production of antibodies is the response of an organism to the gene products of another, nonrelated organism. In this study, the antibody producers were rabbits and the antigen sources were plants.

Antigen preparations were made from 26 collections of 20 species of *Agropyron* (Table I) grown in the Montana State University experimental grass nursery at Bozeman, Montana or in the Plant and Soil Science greenhouse. Two native strains not grown in the nursery are included in Table 1. This nursery was established in the spring of 1961 and samples were taken the springs of 1963, 1964, 1965 and 1966. To prepare the antigens, young leaves were taken from the culms of mature plants with new vegetative growth or from seedling plants which had reached a height of 15 mm. When seedlings were used, several plants were taken as a composite lot in order to have sufficient extract. In the latter case any genetic or environmentally induced differences between plants of a collection would be confounded because of the mixing of antigens from more than one plant. The leaf material was identified as to source and taken to the laboratory where it was washed twice in distilled water then blotted dry. After blotting, the leaves were placed in a metal cylinder one inch in diameter and four inches long, chopped firmly by hand and then pressed

Explanation of Accession Numbers:

MONT = Herbarium of Montana State University, Bozeman, Montana. (Lanjouro and Stafleu 1954).

Table I (cont'd)

Explanation of Accession Numbers (cont'd)

P & A	= Seed collection of the U.S.D.A., Soil Conservation Service, Pacific Region, Plant Material Center, Washington State University, Pullman, (P), Washington, and SCS Southwestern Region, Albuquerque (A), New Mexico.
P.I.	= Seed collection of the U.S.D.A., A.R.S., New Crops Research Branch, Crops Research Division, Plant Introduction Stations, Western Region, Pullman, Washington and North Central Region, Ames, Iowa.
U	= Univalent.
n, 2n	= As is customary in reporting chromosome numbers, n-numbers represent data from meiotic and 2n-numbers data from mitotic studies.
s*	= Indicates material from several seedlings which was bulked to have sufficient material for use.
6-3	= Plant number three in accession number 6.

with 2,500 psi using an hydrolic jack. Approximately 50 grams of this material could be squeezed at a time, although smaller amounts were treated satisfactorily. Fifty grams of this material yielded up to 10 ml. of crude extract.

The crude extract was placed in small sterile vials in 1 ml. aliquots and was immediately frozen at -20°C. until used. No preservative was used. To prepare the crude extract for injection, the material was thawed and centrifuged two minutes at 1,500 rpm (325 G) to remove chloroplasts and fragments of cell wall. All extracts were discarded after having been thawed the second time due to deterioration of antigenic material.

Antisera were produced in New Zealand white rabbits in response to injected extracts. The injections were given subcutaneously near the lymph glands in the shoulders and in the lumbar region. Each injection aliquot was divided into four portions with one portion injected into each of the four regions of the rabbit. No adjuvant was used. The injections were given in weekly series beginning with 0.5 ml., then 1 ml., 2 ml., 3 ml. and a final 4 ml. injection. Booster injections of 1 ml. were given approximately once a week to maintain a high antibody level. Rabbits were kept in individual cages. Rabbits of both sexes were used.

Seven days following the last injection, and weekly after each booster as needed for study, the rabbits were bled from the lateral ear vein. The arteries and veins were dilated with xylene or acetone. The lateral ear vein was opened with a sterile razor blade and the blood was collected in a sterile petri dish. Forty to 60 ml. of whole blood were

taken at each bleeding. Direct pressure with sterile cotton was sufficient to allow the wound to close. Care was taken to remove all traces of xylene from the ear.

The blood was allowed to coagulate in the covered petri dish for about three hours and then the serum was centrifuged at 3,000 rpm (1500 G) for twenty minutes to remove remaining erythrocytes, leucocytes and platelets. The serum was divided into 1 ml. portions, placed in small vials and frozen at -20°C. No preservative was added. Each container was marked with the date of bleeding and the rabbit number. Each bleeding was treated as a separate lot. After being thawed twice, the serum was either used or discarded.

A modification of the gel-diffusion technique described by Ouchterlony (1948) was used to detect differences between plants. The gel-diffusion plates were 90 mm. in diameter with agar poured to a depth of approximately 1.7 mm. The agar was prepared as a 0.6% (W/v) solution of "Ionagar" No. 2 (Oxoid Consolidated Laboratories, Inc., Chicago Heights, Ill.) dissolved in a 0.9% saline solution buffered to a pH of 7.2 with sodium barbitol (vernol) and HCl in distilled water. One part in 5,000 of sodium azide was added as preservative. After dissolving the agar in the buffered saline, 11 ml. of the solution were pipetted onto sterile petri dishes. The prepared plates were allowed to stand for several hours before the wells and trench were made. The plates were cut following the design of Creel et al. (1965) and filled with the appropriate serum and antigen extracts. To test several antisera against a single antigen complex a plate with eleven wells was used (Figure 15). The wells were

made with a #3 cork borer tapered to the inside and were 8 mm. in diameter with the outside wells being 8 mm. from the center wells. The three center wells were filled with antigenic material and the outside wells filled with antisera. The plates were allowed to stand 48 hours at room temperature (20°C. to 25°C.). During this incubation period the antigens and antibodies diffused through the gell. Precipitate lines formed where specific antigens and antibodies met in appropriate concentration.

At the end of the incubation period, the gel-diffusion plates were read immediately or stored at 4°C. up to a week until they could be interpreted. The gel-diffusion plates were read in a darkened room by allowing fluorescent light to pass through the agar at an oblique angle, making the lines clearly visible.

After the initial reading, the plates were flooded with distilled water for six or more hours to wash out unreacted proteins such as gamma globulins and hemoglobins. The distilled water was removed by vacuum and immediately replaced with 0.9 (w/v) NaCl in distilled water. The saline solution was changed two or three times and allowed to stand overnight to insure good flushing of residual globulins (Jutila 1966). At each change of fluid, a crop of merthiolate was added to each plate to retard bacterial and fungal growth. The agar was floated out of the petri dish with distilled water and onto a lantern slide (3 1/4 x 4 1/4) after which the agar was allowed to dry. At this point the slides could be stored indefinitely.

To prepare the slides for staining, they were pretreated by

flooding with 2% glacial acetic acid (2/98 v/v) and held for five minutes. The slides were then stained in 0.5% amido schwartz solution [0.5% amido schwartz (National Aniline) dissolved in 100 ml of 9 parts methanol to 1 part glacial acetic acid (9/1 v/v) then filtered before use] for one hour. The slides were next destained by washing in 9/1 (v/v) methanol / glacial acetic acid solution four to five times. The slides were left in the last wash overnight and then dried (Jutila 1966). The stained slides were projected onto a screen and compared with the original interpretation. All plates were run in duplicate. The four expected precipitate patterns discussed by Ouchterlony (1964) are diagramed in Figure 1.

In the present study four hybrids discussed by Allderdice (1965) and five putative hybrids were studied (Table II) by comparing leaf antigenic material from the parent plants with leaf antigenic material from the hybrid or putative hybrid. The parent plants of hybrid A. brachyphyllum X A. riparium were not available and plants of the same species were used in the comparison. All hybrids and putative hybrids were tested with antisera from rabbits 10-3 and 36-5. The species and animals used for antibody production are listed in Table III.

To test the serological relationship of some species of Agropyron containing or suspected of containing the "S" genome, four antisera were absorbed or partially absorbed with leaf antigenic material from a local population of A. spicatum n=7 from Belgrade, Montana. Antisera were absorbed by mixing antigenic material with the antisera and allowing the mixture to incubate at 37°C. for four hours. The antigenic materials re-

acted with their specific antibodies forming a precipitate. After incubation the precipitate was spun down by centrifugation (325 G.) and discarded. The absorbed antiserum was used to test for antigenic material not contained in A. spicatum n=7.

To estimate the amount of homozygosity and heterozygosity present in the plants studied, an estimate of the breeding behavior was necessary. One method used to study breeding behavior is to determine the amounts of seed set in open-pollination versus that set under conditions of forced self-pollination. To determine the amount of self-fertility of various Agropyron species, tests were carried out during the summers of 1962, 1963, 1964, 1965 and 1966. Plants were isolated by means of isolation chambers (Creel and Schulz-Schaeffer 1963), individual heads were placed in glassine bags, or groups of five or more spikes were placed in heavy waterproof craft paper bags designed for corn pollen. In the latter case, the corn pollen bags were supported by heavy bamboo stakes, with a wire insert to keep the bag open and allow free movement of pollen. The bags were agitated daily to insure adequate pollen distribution. Self-pollination and open-pollination seed set was counted for each plant except for the year 1962 when only open-pollination counts were made and the year 1965 when only self-pollination counts were made. The percentage seed set, percentage open-pollination, percentage self-pollination and the percentage self-fertility were calculated for each strain.

Set notation can be used to describe serological reactions. The definitions for symbols and operations useful and applicable to a serological system are established below:

V denotes the universal set. In this study V has meaning only when qualified by a subscript.

V_{10-3} denotes the finite set of all possible antigen-antibody reactions with antiserum 10-3. The subscript 10-3 refers to the antisera used.

$\emptyset$ denotes the empty set.

A denotes the set of antigens from a particular plant which will cross-react with an antiserum. Other capital letters are similarly defined. $A = \{X_1, X_2, \ldots, X_n\}$

A' denotes the complement of A; it is the set of antigen-antibody reactions not found in the set A. This has meaning only in reference to a particular V.

$\cup$ denotes the union operation. Thus $A \cup A' = V_x$. The union of two sets is the set of all elements that are in at least one of them.

$\cap$ denotes the intersection operation. Thus $A \cap V = A$. The intersection of two sets is the set of all elements common to both sets.

a_n denotes a subset of A. a_n may contain 0, 1, 2, or more elements (antigenic substances). $a_n = \emptyset$ and $a_n = A$ are allowable.

$\supset$ "is a subset of the set". Thus $a \subset A$ and $A \supset a$ would read "a is a subset of the set A". Also $a \not\subset A$ would read "a is not a subset of the set A".

Precipitate lines are formed on a plate due to antigen-antibody interactions. When using set notation to describe these antigen-antibody interactions all connecting lines on a plate will be designated as a subset. For a comprehensive discussion of set notation see Fine (1965).

Moritz (1960) with antiphylaxis techniques characterized the reactions of a wheat-rye hybrid in the following form:

$$WR = wr_1 + wr_2 + wr_3$$

$$W = wr_1 + wr_2$$

$$R = wr_2 + wr_3$$

Set notation may be used to describe these results. Let WR be the set of antigenic material in the wheat-rye hybrid, W the set of antigenic material found in the wheat and R the set of antigenic material found in the rye. wr_1 and wr_2 are subsets of W, wr_2 and wr_3 are subsets of R and wr_1, wr_2 and wr_3 are subsets of WR. Each subset contains one or more antigens. The formula may then be written:

$$W \cup R = WR \quad \text{or} \quad \{wr_1, wr_2\} \cup \{wr_2, wr_3\} = \{wr_1, wr_2, wr_3\}$$

The expected pattern would be for the hybrid to contain all the antigenic material found in the female parent plus all the antigenic material found in the male parent. When antigens have been tested with more than one antiserum and within each antigen-antibody reaction a subset such as a_1 is described, there is no reason to expect a_1 found in V_x to to be equal to a_1 found in V_y. Hybrid plants are expected to contain all the antigentic responses of both parents. This may be shown as the union operation. For example in the wheat X rye hybrid (Moritz 1960) $WR = W \cup R$.

A putative hybrid that is in fact the result of selfing should be identical to the seed parent in its serological response.

It is assumed that:

1. Cross reacting antigens are identical or nearly identical and indicate a phylogenetic relationship between these antigens.

2. No cross reaction can produce more lines than the reference reaction.

3. Antigens are not masked by dominance or epistatic effects.

An effort was made to duplicate the antiserum produced by rabbit 10-3 (Creel et al. 1965) with two unrelated rabbits (009 and 010) the same age. The rabbits were not from the same source as rabbit 10-3. The two rabbits were treated identically with antigenic material from plant 10-3. Identical results were not obtained. Four rabbits (025, 026, 027 and 028) were obtained from the same litter and treated identically with antigenic material from plant 30-10, _A. desertorum_. No differences in titer or number of lines could be detected.

EXPERIMENTAL RESULTS

I. Hybrids and Putative Hybrids

To test five controlled putative hybrids and four known hybrids (Allderdice 1965) two antisera were chosen as common testors. The use of two antisera as common testors was to obtain results which could be compared with each other. Each antiserum has antibodies which may or may not be found in any other antiserum. If antiserum specific for a hybrid or putative hybrid was induced, then only experiments using that particular antiserum could be compared. The antisera were chosen because both were capable of strong cross-reactions with all _Agropyron_ antigenic material tested.

Four known hybrids analyzed by Allderdice (1965) were tested by plating the leaf extract of the parent plants next to the leaf extract of the hybrid. Three hybrids: _A. caninum_ X _A. latiglume_, _A. caninum_ X _A. riparium_ and _A. semicostatum_ X _A. trachycaulum_ behaved as expected. When tested with antisera from rabbits 10-3 and 36-5 all lines were held in common with all three plants. (Figure 2).

The hybrid _A. brachyphyllum_ X _A. riparium_ was tested against a plant of the same collection of _A. brachyphyllum_ (3-4) and a plant from another strain of _A. riparium_ (62a-4). Type II reactions were found when tested against antiserum 10-3 and type III reactions were found when tested against antiserum 36-5. Possible intraspecific variation among plants of _A. brachyphyllum_ and among plants of _A. riparium_ is suggested by these data. This implies that whenever

possible the exact parents of a hybrid should be used. (Figure 3).

Five putative hybrids were tested against their known seed parent and the supposed pollen parent using antisera from rabbits 10-3 and 36-5.

The putative hybrid A. intermedium (34a-1) X A. intermedium (44-2) and the seed parent (34a-1) showed one precipitate line that (44-2) did not have when tested against antiserum 10-3 and two precipitate lines not found in (44-2) when tested against antiserum 36-5 (Figure 4).

For the A. intermedium (34a-1) X A. intermedium (44-2) putative hybrid the antigen sets are assigned A. intermedium (34a-1) I_1, A. intermedium (44-2) I_2 and the putative hybrid I_h. Two universal sets V_{10-3} and V_{36-5} are involved. In the universe V_{10-3} and the universe V_{36-5}, $I_1 \supset i_1, i_2$ and $I_2 \supset i_1$ where i_1 is the set of all common lines. If I_h is a hybrid then it should equal $I_1 \cup I_2$. If I_h is a self rather than a hybrid then it should equal the seed parent I_1. In both the universe V_{10-3} and the universe V_{36-5}:

$$I_h = I_1 \cup I_2 = I_1.$$

Therefore I_h is either a hybrid or it is a self. The hybridity of this plant cannot be determined by these tests.

The two collections of A. intermedium did not behave in an expected manner in that they were serologically different when tested with each of the antisera used as common testors. No differences between the parent plants were expected. Plant 34a-1 contained one

antigen capable of reacting with 10-3 antiserum which was not found in 44-2 and two antigens capable of reacting with 36-5 antiserum not found in 44-2. This represents a definite genetic difference between plants of the same species.

The suspected hybrid A. ciliatiflorum X A. cristatiforme and the seed parent A. ciliatiflorum each showed two precipitate lines that A. cristatiforme did not have when tested with antiserum 10-3. When tested with antiserum 36-5, the putative hybrid and A. ciliatiflorum showed one precipitate line not found in A. cristitiforme; and A. cristatiforme showed one precipitate line not found in the putative hybrid or A. ciliatiflorum. These different precipitate lines appear on the plate as crossed lines (Type II reaction) and are shown in Figure 5.

For the putative hybrid A. ciliatiflorum X A. cristatiforme the antigen sets are assigned A. ciliatiflorum C_i, A. cristatiforme C_r and the putative hybrid C_h. In the universe V_{10-3}, $C_i \supset c_1$, c_2 and $C_r \supset c_1$. This is unexpected as 10-3 is also A. cristatiforme and C_r should come close or equal to V_{10-3}. This is another indication of unexpected intra-specific variation. In the universe V_{36-5}, $C_i \supset c_1$, c_2 and $C_r \supset c_1$, c_3. $C_h \supset c_1$, c_2 in both V_{10-3} and V_{36-5}. In this case $C_h = C_i$ and $C_h \neq C_i \cup C_r$. It is concluded that C_h is not a hybrid.

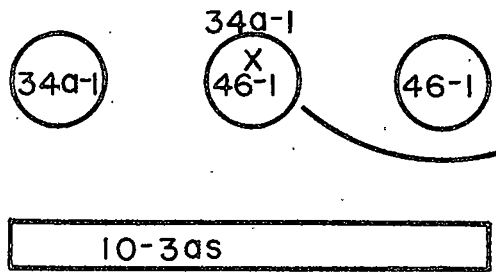
8 common lines

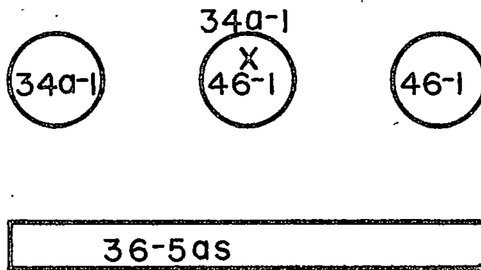
Fig. 5 Drawing of the serological plates showing the difference observed between A. *ciliatiflorum*, A. *cristatiforme* and their putative hybrid. Note the type II reaction shown between A. *cristatiforme* and the putative hybrid when tested against antisera from rabbit 36-5. The dotted lines indicate very weak reactions.

When the putative hybrid *A. intermedium* X *A. junceum* was tested with its supposed parents against antiserum 36-5, all lines were in common. The pollen parent, *A. junceum* showed a precipitate line that the putative hybrid and *A. intermedium* did not have when tested against antiserum 10-3 (Figure 6).

The putative hybrid *A. intermedium* X *A. junceum* is assigned the following set of symbols. *A. intermedium* I_3, *A. junceum* J and the putative hybrid IJ. In the universe V_{10-3}, $I_3 \supset j_1$ and $J \supset j_1, j_2$.



10 common lines



10 common lines

Fig. 6 Drawing of the serological plates showing the difference observed between *A. intermedium*, *A. junceum* and their putative hybrid.

In the universe V_{36-5}, $I_3 \supset j_1$ and $J \supset j_1$. The hybrid was found to contain the subset j_1 in the universe V_{36-5} and $IJ \supset j_1$ in the universe V_{10-3}. The formula for the universe V_{36-5} is:

$$IJ = I_3 = J.$$

The formula for the universe V_{10-3} is:

$$IJ = I_3 \text{ and } IJ \neq I_3 \cup J.$$

It is concluded that IJ is not a hybrid. It does not contain all the antigens found in the supposed male parent.

The putative hybrid _A. intermedium_ X _A. elongatum_ and the seed parent _A. intermedium_ showed a precipitate line not found in the pollen parent _A. elongatum_ when tested against antiserum 10-3. When tested against antiserum 36-5, _A. elongatum_ showed a precipitate line not found in either the hybrid or the seed parent (Figure 7).

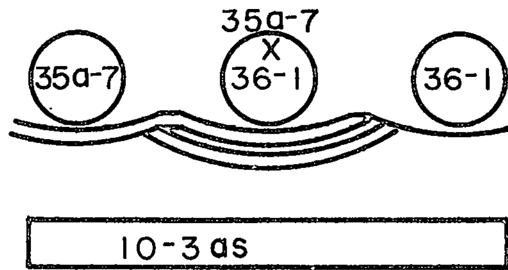
The putative hybrid _A. intermedium_ X _A. elongatum_ is assigned the following set of symbols. _A. intermedium_ I_4, _A. elongatum_ E and the putative hybrid IE. In the universe V_{10-3}, $I_4 \supset i_1$, i_2 and $E \supset i_1$. In the universe V_{36-5}, $I_4 \supset i_1$ and $E \supset i_1$, i_3. The hybrid was found to contain the subsets i_1, i_2 in the universe V_{10-3} and $IE \supset i_1$ in the universe V_{36-5}. The formula for the universe V_{10-3} is:

$$IE = I_4 \text{ and } IE = I_4 \cup E$$

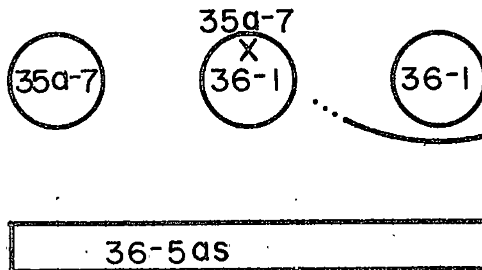
The formula for the universe V_{36-5} is:

$$IE = I_4 \text{ and } IE \neq I_4 \cup E.$$

It is concluded that IE is not a hybrid. It does not contain all



9 common lines



8 common lines

Fig. 7 Drawing of the serological plates showing the difference observed between A. intermedium, A. elongatum and their putative hybrid.

the antigenic material found in the supposed male parent.

The putative hybrid _A. spicatum_ (n-14) X _A. pycnanthum_ was tested with its presumed parents and the supposed pollen parent _A. pycnanthum_ showed two precipitate lines not in common with the seed parent or the supposed hybrid when tested against antiserum 10-3, and one precipitate line not in common with the seed parent or the putative hybrid when tested against antiserum 36-5 (Figure 8).

The putative hybrid _A. spicatum_ X _A. pycnanthum_ is assigned the following set of symbols. _A. spicatum_ S, _A. pycnanthum_ P and the putative hybrid SP. In the universe V_{36-5}, $S \supset s_1$ and $P \supset s_1, s_2$. The suspected hybrid was identical to S in both V_{10-3} and V_{36-5}. The formula for both V_{10-3} and V_{36-5} becomes:

$$SP = S \text{ and } SP \neq S \cup P.$$

It is concluded that SP is not a hybrid. It does not contain all the antigenic material found in the supposed pollen parent.

II. Serological Analysis of the B Genome

Individual plants of 11 species of _Agropyron_ (Table IV) were tested against four different antisera (Table V) which had been absorbed or partially absorbed with antigenic material from _A. spicatum_ (n=7). For these tests, S denotes the set of antigen-antibody responses with the diploid _A. spicatum_ antigenic material. S', the complement to S, is all the rest of the possible reactions to a particular antiserum. This may be described by:

$$V_x = S \cup S' \text{ and } S' = V_x - S.$$

Rabbit No.	Species Used to Induce the Production of Antibodies	Plant No.
147-S	_A. dasystachyum_	147-S
10-3	_A. cristatiforme_	10-3
68-5	_A. sibiricum_	68-5
025	_A. desertorum_	30-10

This experiment was designed to test the possibility that the B genome found in A. trachycaulum, A. arizonicum, and A. caninum may be a modification of the S genome represented by the diploid A. spicatum as proposed by Schulz-Schaeffer and Jura (1967). By removing those antibodies that will react with antigenic material from A. spicatum (n=7) an estimate of the genes not present (or inactive), which will make a serological response, will be obtained. Each serological precipitate line observed on the plates may be described as:

$$S' \cap A = a_1 \text{ where } a_1 \text{ is a subset of } A.$$

Two antisera, 10-3 and 68-5 each had an antibody with a very high titer which along with the low titer of the antigenic material in A. spicatum (n=7) which would react with this antibody, resulted in a very low titer serum when the antibody was removed. This was due to excess dilution of the serum with the leaf extract. Partially absorbed antisera were used (Figure 9). To interpret the results using the partially absorbed serum, the number of lines with A. spicatum (n=7) was subtracted from the total number of lines observed.

In the absorption tests the following sets are designated; A. spicatum (n=7) S, A. spicatum (n=14) S_4, A. arizonicum A, A. brachyphyllum B, A. caninum C_a, A. ciliatiflorum c_1, A. latiglume L, A. dasystachyum D, A. panormitanum P, A. riparium R, A. subsecundum S_u and A. trachycaulum T.
