Abstract:

The replacement of first row elements by second row elements (e.g. S for O) in electron donating groups in conjugated organic materials has been shown to produce an enhancement of the nonlinear response. Amino functionalities have been utilized as strong donors in the design of molecules for both second and third order NLO applications. In the present work N (Nitrogen) has been replaced by P (Phosphorus) in various chromophore functionalities. A series of bis-(diphenylphosphino) diphenyl polyenes with up to five double bonds, a bis-(diphenylphosphino)-PPV dimer, and a diphenylphosphino DANS equivalent have been synthesized. In addition, the first generations (G0) of two types of dendrimers were made by a divergent approach. The first type is a series of three arm dendrimers with stilbene type units. The second type is a series of three arm dendrimers with PPV type units.

These new molecules were compared to the N equivalents in several characteristics such as absorption, organic light emitting diodes (OLED), nonlinear optical properties, two-photon absorption, and reverse saturable absorption.

It was found out that diphenylphosphino substituents behave as weak electron-withdrawing groups despite the lone pair of electrons. Compared to N, the lone pair of electrons of P participates weakly in the conjugation of π -systems, which results in a blue shift in λ .

DESIGN AND SYNTHESIS OF NEW NONLINEAR OPTICAL
CHROMOPHORES INCORPORATING DIPHENYLPHOSPHINO

ACKNOWLEDGEMENTS

I want to thank Dr. Charles Spangler for all the years of support he gave me during the time I was in both Northern Illinois University and then in Montana State University. Also, for the good times and the excellent food we had in the chemistry conferences we went to. I want to thank the members of the Spangler Group for the conversations we had about chemistry problems we experienced during our research and also for conversations not related with our work that allowed me to learn more about this country and its culture.

I would like to acknowledge the partial support of this research by the Air Force Office of Scientific Research under grants F49620-96-1-0440 and F49620-97-1-0413. Also, to the Graduate School and The Department of Chemistry for the support and financial assistance.

Finally, I want to thank my wife, Valerie, for all her love and support during my graduate studies. You showed me patience and understanding, when I had to spend long hours studying and working in the laboratory, for which I am very grateful. Thank you for being next to me all this time.

THG: third harmonic generation

E-O: electro optics

Tg: glass transition temperature

ITO: indium tin oxide

HTL: hole transport layer

ETL: electron transport layer

EL: electroluminescence

RSA: reverse saturable absorption

TPA: two-photon absorption

ISC: intersystem crossing

TS: possible transient state

EWG: electron withdrawing group

EDG: electron donating group

PIA: photo induced absorption

ABSTRACT

The replacement of first row elements by second row elements (e.g. S for O) in electron donating groups in conjugated organic materials has been shown to produce an enhancement of the nonlinear response. Amino functionalities have been utilized as strong donors in the design of molecules for both second and third order NLO applications. In the present work N (Nitrogen) has been replaced by P (Phosphorus) in various chromophore functionalities. A series of bis-(diphenylphosphino) diphenyl polyenes with up to five double bonds, a bis-(diphenylphosphino)-PPV dimer, and a diphenylphosphino DANS equivalent have been synthesized. In addition, the first generations (G0) of two types of dendrimers were made by a divergent approach. The first type is a series of three arm dendrimers with stilbene type units. The second type is a series of three arm dendrimers with PPV type units.

These new molecules were compared to the N equivalents in several characteristics such as absorption, organic light emitting diodes (OLED), nonlinear optical properties, two-photon absorption, and reverse saturable absorption.

It was found out that diphenylphosphino substituents behave as weak electron-withdrawing groups despite the lone pair of electrons. Compared to N, the lone pair of electrons of P participates weakly in the conjugation of π -systems, which results in a blue shift in λ_{max} .

INTRODUCTION

The synthesis of polyacetylene (1) by Shirakawa¹ in the 1970s permitted the study of the chemistry, physics and applications of conducting polymers. This has resulted in an increasing interest in electroactive materials that has given us a better understanding of the formation and stabilization of the charge states and the nature of the insulator-metallic transition upon chemical or electrochemical doping. It is currently accepted that polymers like polyacetylene are dominated by polaronic (radical-cations or radical-anions) or solitonic species, while polymers such as polythiophene (2) and poly[p-phenylenevinylene] (3) are dominated by bipolaronic species (di-ions) in the conducting state. The insulator-conductor transitions due to an oxidative doping have been linked to the appearance of new midgap states, which seem to be characteristic of π -conjugated polymers in general. It has been demonstrated that electroactive polymers also have unique optical properties.² For this reason, the nature of charge-state formation and stabilization in extended π -systems and the relationship of the electron delocalization and polarization to electronic and/or photonic properties is an ongoing area of study.

Several research groups have shown that electroactive polymers and oligomers possess enhanced nonlinear optical properties. The NLO properties rise from an interaction of an electric field E of light with matter that can be described on the molecular level by equation 1,

$$P = \alpha E + \beta E E + \gamma E E E + \dots \quad \text{eq. (1)}$$

where P is the induced polarizability by the electric field, α is the linear polarizability, and β and γ are the first and second order hyperpolarizability respectively.³ The nonlinear response is generally very weak and it is only possible to observe in some NLO materials when strong electromagnetic fields are used, as the one obtained with a coherent laser beam causing a polarization response in the π -electron cloud of conjugated organic molecules. This polarization response is intensity-dependent and thus non-linear. In a practical sense, this interaction produces a temporary change in the material optical properties, such as index of absorption or refraction, which are present as long as the electric field is present.

In bulk materials, like polymer films, the non-linear susceptibilities $\chi^{(2)}$ and $\chi^{(3)}$ are third and fourth order tensors respectively, that relate all components of the polarization vector (P) to all components of the electric field vector (E) as described by equation 2:

$$P(E) = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \dots \quad \text{Eq. (2)}$$

Nonlinear optical properties can be assessed by a variety of techniques, which probe the NLO response of a system. Two common ways of doing this is by Third Harmonic Generation (THG) and Electric Field Induced Second Harmonic generation (EFISH) measurements. THG³ is a process that describes production of the third harmonic of the incident laser frequency and is related to the magnitude of the third order hyperpolarizability. EFISH³ is a technique where a strong dc electric field is applied to a sample, causing the molecules to orient the dipole moment with the interacting applied field. EFISH has contributions from both $\chi^{(2)}$ and $\chi^{(3)}$; however, for centrosymmetric structures or structures with zero second-order nonlinearity, the EFISH generation are derived from the third order nonlinearity.

Results of studies on γ , the third order hyperpolarizability, show that it increases with increasing conjugation length.⁴ However, this conjugation can be limited to an effective conjugation length that is less than the formula conjugation length due to steric or conformational effects that may cause twisting out of planarity and a loss of orbital overlap.⁵ It has been postulated that γ enhancement may be possible by the incorporation of polaronic and bipolaronic charge states in conjugated π -systems. This prediction has been supported by more refined calculations, and such enhancement has been experimentally verified for both small molecules in solution and polymers.^{6,7} The solubility of dibutyl-substituted dithienylpolyenes series has allowed the determination for the first time of length-dependence on bipolaronic species studies. Nonlinear optical studies of the oxidative doping of these series have confirmed the prediction of γ enhancement by bipolaron formation. These materials are among the most nonlinear small molecules yet studied (γ values approaching 10^{-30} esu). Since the polarizability of a π -conjugated system is related to the extent of π -electron delocalization in the system, the possibility of coupling bipolaronic enhancement of $\chi^{(3)}$ with three-dimensional charge delocalization in dendritic macromolecules promises to be a seminal approach to the design of new NLO materials, and may allow third-order NLO macromolecules to compete for the first time with electric-field poled second-order polymers in a variety of applications. These materials can then be used in a variety of photonic applications such as eye protection via reverse saturable absorption or two photon absorption, in optical wave-guiding, third harmonic generation for nonlinear optical (NLO) applications, for electrochromic thin films for high contrast electrochromic applications, and finally in organic light-emitting diodes (OLEDs).

HISTORICAL SECTION

Structure-Property Relationship for Third-Order Non-linear Optical Activity

Over the past 10 years there have been tremendous efforts to synthesize organic molecules with high third-order optical non-linearity^{8,10}. These synthetic efforts have been focused in finding the right structure-property relationships that correspond to molecules with an enhanced NLO response. From these studies it has been found that the second hyperpolarizability is proportional to the extent of electron delocalization in molecules containing π -electron systems¹¹. In an attempt to model and predict the consequences of increasing conjugation, several researchers have made use of a power relation of the form^{12,13},

$$\gamma \propto N^a$$

where N is the number of repeat units, like double bonds, carbon atoms, or length of the molecule. Beratan et al.¹³, using a Huckel approach, have shown that γ increases rapidly for polyenes as conjugation increases to 10-15 repeat units, and then more slowly up to 40 repeat units. Based on ab initio calculations for a series of polyenes up to C₂₂H₂₄, Hurst and coworkers¹⁴ found that γ was proportional to chain length with power dependence of 4.0; however, this dependence levels off as N increases. Garito and coworkers¹⁵ calculated a power law dependence of γ on chain length in the order of 4.6 ± 0.2 . They suggest that only conjugation sequences of intermediate length (100 Å) are needed in order to obtain large values of $\chi^{(3)}$. Also, Prasad¹⁶ has measured γ for a series of polythiophene oligomers by degenerate fourwave mixing (DFWM) in solution and found a power law dependence for γ of 4. He also concluded that γ levels off with increasing N. In addition, from $\chi^{(3)}$ measurements on poly (3-dodecylthiophene) he

found that the effective conjugation, for NLO purposes, did not extend much beyond 10 repeat units, and that similar measurements for poly (p-phenylene) showed a leveling off of $\chi^{(3)}$ at the terphenyl level (N=3). All this suggests that it may not be necessary to synthesize a chain with very long number of repeat units in order to produce high third-order nonlinearity¹⁷.

Cheng et al.¹⁸, in an attempt to understand what structural parameters most affect γ , made extensive measurements on benzene, styrene, and stilbene derivatives. Tables 1, 2, and 3 show the results from that study.¹⁸ These studies were focused on experimental measurements on molecules where the following parameters were systematically changed to correlate their influence on the nonlinear properties.

monosubstituted benzene and stilbene derivatives.¹⁸ In the case of benzene, the most striking observation is that, except in N,N-dimethylaniline and julolidine, all donors groups are found to be ineffective in inducing charge and polarization asymmetry. This is seen in the small values for β and γ . Examination of the second order nonlinear property (γ^{EFISH} and γ^{THG} values) in Table 1 show that for monosubstituted benzenes, both values change in parallel, indicating a limited dipole contribution to EFISH signal. This is partly due to the small dipole moments. The situation is the same for halogen derivatives. The ineffectiveness of donors in inducing asymmetry may be attributed to two factors. Apart from the dimethylamino group and the bridged structure in julolidine, the connecting atom in all the donors, including the amino, is sp^3 hybridized. Due to the tetrahedral geometry, there is not an efficient overlap between the lone pair containing donor and the π orbitals of the benzene ring. Besides, these donor substitutions only result in minimal extension of the overall conjugation¹⁹. On the other hand, electron withdrawing groups are found to be more effective. Their efficiencies increase in the order of SO_2CH_3 , SO_2F , CN, CHO, COCF_3 , NO, NO_2 , and $\text{CHC}(\text{CN})_2$. The reason for the effectiveness of the accepting groups may be the proper hybridizations and longer extensions of the benzene conjugation.

It is also interesting to investigate the cooperative effects of donor and acceptor groups by studying para-disubstituted benzene and 4,4'-disubstituted stilbene. Tables 2 and 3 show the results on these systems performed by Cheng et al¹⁸. In all cases there is a significant increase of β and γ compared to the monosubstituted fragments. This is the well-recognized enhancement resulting from the charge transfer (CT) interactions between donor and acceptor groups²⁰. Charge transfer interactions between substituents can be seen as resonance structures that connect charge-neutral and charge-separated states with alternating single and double bonds.
